Trading and Shareholder Voting[*]

September 27, 2019

Abstract

We study shareholder voting in a model in which trading affects the composition of the shareholder base. In this model, trading and voting are complementary, which gives rise to self-fulfilling expectations about proposal acceptance. We show three main results. First, increasing liquidity and trading opportunities may reduce prices and welfare, because it allows shareholders with more extreme preferences to accumulate large positions and impose their views on more moderate shareholders through voting. Second, prices and welfare can move in opposite directions, which suggests that the former is an invalid proxy for the latter. Third, delegation of the decision to a board of directors may strictly improve shareholder value. However, the optimal board is generally biased, should not be representative of current shareholders, and may not always garner voting support from the majority of shareholders.

"Shareholders express views by buying and selling shares; (...) The more share-holders govern, the more poorly the firms do in the marketplace. Shareholders' interests are protected not by voting, but by the market for stock (...)." (Easterbrook and Fischel (1983), pp. 396-397)

1 Introduction

Shareholder voting is important for corporate governance, and recent regulatory reforms in advanced economies have empowered shareholders in an effort to constrain managerial discretion.[1] As a result, shareholders not only elect directors, but frequently vote on executive compensation, corporate transactions, and changes to the corporate charter. This shift of power from boards to shareholder meetings takes for granted that shareholder voting increases welfare and firm valuations by aligning the preferences of those who make decisions with those for whom decisions are made – a form of "corporate democracy."[2] However, unlike the political setting, a key feature of the corporate setting is the existence of the market for shares, which allows investors to choose their ownership stakes based on their preferences and the stock price, and thus, who gets to vote on the firm's policies is fundamentally linked to voters' views on how the firm should be run. While the literature has looked at many important questions in the context of shareholder voting, it has so far not examined the effectiveness of voting if we acknowledge that the shareholder base forms endogenously through trading.[3] The main goal of this paper is to examine the link between trading and voting and its implications for company valuations and welfare, and to highlight how the effectiveness of shareholder voting vis-a-vis board decision-making is affected by the firm's trading environment.

Specifically, we study the relationship between trading and voting in a context in which

---

[1] Cremers and Sepe (2016) make the same observation and review the large legal literature on the subject (see also Hayden and Bodie (2008)). The finance literature has assembled a wealth of empirical evidence on this shift, including the discussion on the effectiveness of say-on-pay votes, surveyed by Ferri and Göx (2018), reforms to disclose mutual fund votes in the United States (e.g., Davis and Kim (2007); Cvijanovic, Dasgupta, and Zachariadis (2016)) and the introduction of mandatory voting on some takeover proposals in the UK (Becht, Polo, and Rossi (2016)).

[3] Karpoff (2001) surveys the earlier and Yermack (2010) the later literature on shareholder voting.

shareholders differ in their attitudes toward proposals. We provide several key insights. First, trading aligns the shareholder base with the expected outcome, even if the expected outcome is not optimal. As a result, there can be multiple equilibria, so that similar firms can end up having very different ownership structures and taking very different strategic directions – a source of non-fundamental indeterminacy. Second, while higher market liquidity and trading opportunities increase the ability of shareholders to gain from trade, they may nevertheless reduce welfare by allowing the shareholder base to become more extreme, so that the views of more extreme shareholders prevail over those with more moderate attitudes. Third, changes in the governance or trading environment of the firm can affect welfare and prices in opposite directions, which suggests that price reactions to voting outcomes may not be a valid empirical proxy for their welfare effects. Finally, and as a result of the above effects, shareholder welfare can be increased if, instead of voting, decisions are delegated to the board of directors. Moreover, the optimal choice between voting and delegation to the board crucially depends on trading opportunities and potential shifts in the shareholder base.

We consider a model in which a continuum of shareholders first trade their shares in a competitive market and then vote on a proposal. Each shareholder's valuation of the proposal depends on an uncertain common value that all shareholders share, but also on a private value that reflects shareholders' different attitudes toward the proposal. After shareholders trade, but before they vote on the proposal, they observe a public signal on the proposal's common value. Shareholders do not have private information.[4] Because of private values, some shareholders are biased toward the proposal and vote to accept it even if the common value is expected to be low; we call them *activist* shareholders. By contrast, other shareholders are biased against the proposal and have a higher bar for accepting it; we call them *conservative*. These different attitudes between shareholders may reflect private benefits from their ties with the company, different social or political views ("investor ideology"), time horizons, risk aversion, and tax considerations.[5] Some commentators even argue that shareholder voting should be seen as a

[4]There is already a literature on information aggregation in voting, e.g., Maug and Rydqvist (2009) and Levit and Malenko (2011).

[5]Matvos and Ostrovsky (2010) analyze mutual fund votes and show that they differ systematically in their support for management. Cvijanovic, Dasgupta, and Zachariadis (2016) analyze the heterogeneity from conflicts of interests of mutual funds that also run companies' pension funds. Some shareholders have interests that set

system to aggregate heterogeneous preferences (Hayden and Bodie (2008)).

We start by analyzing the setting in which shareholders can trade but cannot vote, e.g., if the decision on the proposal is taken by the board of directors. In this case, the equilibrium is unique and can be of two types, depending on the likelihood that the board will adopt the proposal. If the probability of adoption is above a certain threshold, then activist shareholders value the firm more than conservative shareholders and will buy shares from them, whereas in the opposite case, conservatives will buy and activists will sell. Thus, trading allows shareholders who do not agree with the company's decisions to sell to those shareholders who expect their preferred alternative to be chosen.

By contrast, we show that if the decision on the proposal is made by a shareholder vote, i.e., shareholders first trade and then vote, then multiple equilibria can arise. An *activist* equilibrium, in which the proposal is accepted with a relatively high probability, can co-exist with a *conservative* equilibrium, in which the proposal is likely to rejected.[6] Multiplicity arises because voting and trading are complements: If shareholders expect a more activist outcome, i.e., a high likelihood of proposal adoption, the more conservative shareholders sell to the more activist shareholders. As a result, the composition of the shareholder base after trading is more activist and proposals are approved more often, confirming the ex-ante expectations. Similarly, for the same parameters, if a more conservative outcome is expected, then trades occur in the opposite direction, creating a more conservative shareholder base, which approves the proposal less frequently. In both cases, expectations are self-fulfilling. The multiplicity of equilibria sheds light on a new source of non-fundamental indeterminacy and highlights potential empirical challenges in analyzing shareholder voting, since firms with the same fundamental characteristics can have different ownership structures and adopt different policies.

---

them apart from other shareholders, e.g., unions (Agrawal (2012), family shareholders and founders (Mullins and Schoar (2016); Villalonga and Amit (2006)), CEOs, and governments. Bolton et al. (2019) and Bubb and Catan (2019) develop different classifications to capture the cross-sectional variation of shareholders' attitudes to optimal corporate governance. Bushee (1998) and Gaspar, Massa, and Matos (2005) analyze the implications of differences in time horizons between investors. Hayden and Bodie (2008) provide a comprehensive overview of different sources from which conflicts of interests may arise.

[6]Classic examples of multiple equilibrium models in financial economics include Diamond and Dybvig (1983) on bank runs; Calvo (1988) on debt repudiation; and Obstfeld (1996) on currency crises. See Morris and Shin (2000) for a critical evaluation of multiple equilibrium models. We discuss this literature more extensively in Section 4.3.2.

We show that such multiplicity is especially likely when the firm faces low trading frictions and high heterogeneity of the initial shareholder base. In the Conclusion we offer an additional perspective on how shareholders may coordinate if there are multiple equilibria.

Our second set of results explores the price and welfare implications of the trading environment. If shareholders do not vote, e.g., if decisions over the proposal are made by the board, greater opportunities to trade (i.e., higher liquidity, smaller transaction costs, or fewer wealth constraints) always result in higher prices and higher welfare: Shareholder heterogeneity creates gains from trade, and more liquid markets allow more gains from trade to be realized. However, when decisions are made by a shareholder vote, greater opportunities to trade may be detrimental for both, prices and welfare. The reason is that the decision on the proposal depends on the identity of the marginal voter, who is determined by the post-trade shareholder base and the majority requirement. By contrast, aggregate welfare depends on how proposal adoption affects the valuation of the average shareholder who holds shares after trading, and hence welfare is lower when the marginal voter is more different from the average post-trade shareholder. As opportunities to trade increase, the shareholder base becomes more extreme — e.g., the post-trade shareholder base becomes more activist in the activist equilibrium when trading opportunities are larger. This may widen the gap between the marginal voter and the average shareholder and thereby reduce welfare. Similarly, more trading can depress the stock price, because it widens the gap between the marginal voter and the marginal trader, whose valuation sets prices. Hence, voting creates an externality, and more extreme shareholders can impose a loss on the more moderate shareholders.

Importantly, our analysis highlights that prices and welfare may react differently and in opposite directions to changes to the corporate governance or trading environment of the firm. To see the intuition, consider the case in which the marginal voter is moderate and less extreme than the average post-trade shareholder but more extreme than the marginal trader. Then an exogenous change in governance, e.g., an increase in the majority requirement, affects the identity of the marginal voter. This shift either widens the gap with the marginal trader and narrows the gap with the average post-trade shareholder, or the opposite. In those cases, prices increase (decrease) exactly when welfare decreases (increases). This result challenges

the notion that there is a close connection between welfare and prices, which the literature often relies on. It casts doubts on the validity of price reactions as an empirical proxy for the welfare effects of voting on shareholder proposals.

Finally, we examine the optimal allocation of power between boards and shareholder meetings by comparing welfare in the two settings described above – when shareholders trade and vote; and when shareholders trade but decisions are made by the board. The board, like each of the shareholders, is characterized by its attitude toward the proposal.

We define the optimal board as that which maximizes the initial shareholder welfare. We begin by showing that the optimal board is biased relative to the initial shareholder base, especially if trading opportunities are large. Intuitively, the welfare of the pre-trade shareholder base and the post-trade shareholder base is the same, because in a frictionless market gains to buyers cancel losses to sellers. Hence, the welfare of the *pre-trade* shareholders is maximized when the preferences of the average *post-trade* shareholder coincide with those of the decision-maker, in this case the board. Since trading opportunities make the post-trade shareholder base more extreme, the optimal board is biased. We also show that this optimally biased board, as well as a "good enough" board that is sufficiently similar to the optimal board, increase shareholder welfare relative to decision-making via shareholder voting. In other words, the naive logic that whenever the board is biased, decisions should be delegated to shareholders, is not necessarily correct when shareholder trading is taken into account.

Even if it is optimal to delegate decision-making to the board, it is not guaranteed that the majority of shareholders will want to do so given the heterogeneity of preferences between them. To examine this question, we extend the model by adding a stage before the trading stage in which shareholders vote on whether to delegate the decision on the proposal to the board. We show that shareholders may choose not to delegate decision-making to a board that maximizes welfare. This is because with voting before trading, a new externality arises: Shareholders who expect to buy shares after the delegation decision consider not only the implications of delegation for the long-term value of the firm, but also for the short-term price at which they can buy shares from those shareholders who sell. As a result, short-term trading considerations may push these shareholders to elect a suboptimal board in order to benefit

from the lower price.

Overall, we strike a cautious note on the general movement to "shareholder democracy." Since shareholders can trade their shares, giving them voting rights creates a complementarity between voting and trading that gives rise to multiple equilibria. There is no guarantee that shareholders can always coordinate on the welfare-dominant equilibrium. Moreover, even the best voting equilibrium is dominated not only by delegation to an optimal board, but also by delegation to a "good enough" board. Finally, shareholders might make incorrect decisions when delegating their decision-making rights to the board if they give excessive weight to short-term trading considerations. As such, we resonate the critical stance of Easterbrook and Fischel (1983) in the opening vignette and expand on these issues in the Conclusion.

The remainder of the paper is organized as follows. Section 2 surveys the literature. Section 3 introduces the setup. Section 4 first analyzes two benchmarks that consider trading and voting separately, and then characterizes the equilibrium of the model with trading and voting. Section 5 discusses the implications for shareholder welfare and prices. Section 6 examines the benefits of delegating decision-making authority to the board of directors. Section 7 concludes. All proofs are gathered in the Appendix. The Online Appendix discusses a generalization of the model.

2   Discussion of the literature

In this section we discuss the literature that is relevant to trading and voting. Our paper is related to the theoretical literature on shareholder voting (Maug and Rydqvist (2009), Levit and Malenko (2011), Van Wesep (2014), Malenko and Malenko (2019), and Bar-Isaac and Shapiro (2019)). These papers all assume an exogenous shareholder base and then discuss strategic interactions between shareholders based on heterogeneous information, heterogeneous preferences, or both. By contrast, our analysis endogenizes the shareholder base and asks how the voting equilibrium changes if shareholders can trade before voting. Musto and Yilmaz (2003) analyze how adding a financial market changes political voting outcomes. However, in their model voters trade financial claims but not the votes, which is different from the shareholder

context. Overall, our paper contributes to this literature by overcoming an important theoretical challenge when analyzing shareholder voting: Shareholders' valuations and their trading decisions depend on expected voting outcomes, but voting outcomes depend in turn on the composition of the shareholder base, which is endogenous and changes through trading.

We are aware of three strands of the literature that integrate an analysis of shareholder voting with trading in models in which shareholdings are endogenous. The first is the literature on general equilibrium economies with incomplete markets, and Gevers (1974) is the earliest contribution to this literature to the best of our knowledge; subsequent contributions include Drèze (1985), DeMarzo (1993), and Kelsey and Milne (1996). This literature recognizes that shareholders with different preferences will be unanimous and production decisions can be separated from consumption decisions (Fisher separation) only if markets are complete.[7] With incomplete markets, shareholders will generally disagree about the optimal production plans of the firm, since shareholders are not only interested in profit maximization but also in the influence of firms' decisions on product prices (e.g., Kelsey and Milne (1996)). Then the objective of the firm becomes undefined, and the models in this literature introduce governance mechanisms such as voting, blockholders, or boards of directors to close this gap.[8] One important insight from this literature is that shareholder disagreement over companies' policies and governance mechanisms to resolve conflicts between shareholders both originate from incomplete markets. Compared to this earlier literature, we analyze a less general model, which allows us to characterize equilibria beyond existence, analyze the way in which voting and trading interact, derive implications for shareholder welfare, and characterize delegation decisions and their properties.

The second literature analyzes the issues that arise when financial markets allow traders to exercise voting rights without exposure to the firm's cash flows. Kalay and Pant (2009) show that allowing traders to separate voting from cash-flow interests may be beneficial for shareholders if it allows them to extract a larger premium in control contests. Brav and

---

[7]Hirshleifer (1966) shows that Fisher separation obtains in an inter-temporal production economy with complete markets in a state-preference framework.

[8]See Gevers (1974), Drèze (1985), and DeMarzo (1993) on majority voting. Drèze (1985) and DeMarzo (1993) conceptualize the board of directors as a group of controlling blockholders.

Mathews (2011) build a model of such "empty voting" and conclude that the implications for efficiency are ambiguous and depend on transaction costs and shareholders' ability to evaluate proposals. Esö, Hansen, and White (2014) argue that empty voting may improve information aggregation. Our paper is complementary to this literature, since we abstract from derivatives markets and vote-trading and assume one-share-one-vote throughout.[9]

The third literature analyzes blockholders who form large blocks endogenously through trading and affect governance through voice or exit (see Edmans (2014) and Edmans and Holderness (2017) for surveys). However, this literature does not focus on the complementarities and collective action problems that arise in our model, as the majority of this literature focuses on models with a single blockholder. Relative to existing governance models of multiple blockholders (Zwiebel (1995), Noe (2002), Edmans and Manso (2011), and Brav, Dasgupta, and Mathews (2017)), our paper analyzes the feedback loop between voting and trading and how this affects the choice between delegation to a board and shareholder voting.[10]

Broadly, our paper is also related to the literature on the real effects of financial markets (see Bond, Edmans, and Goldstein (2012) for a survey). This literature is mainly concerned with price formation and information aggregation in financial markets, and asks how information is transferred from markets to decision-makers, where the preferences of decision-makers are assumed to be exogenous. Our paper does not feature information aggregation and instead highlights a new force through which financial markets have real effects by allowing the shareholder base to shift: The preferences of the main decision-maker are endogenous and result from trading.

---

[9]Burkart and Lee (2008) provide a comprehensive survey of the theoretical literature on the one-share-one-vote structure.

[10]Garlappi, Giammarino, and Lazrak (2017; 2019) analyze group decision-making about investment projects and show how trade among group members may overcome inefficiencies from differences in beliefs. These papers focus on the dynamics of group decision-making and do not feature the mechanisms and results that arise in our model.

3 Model

Consider a firm with a continuum of measure one of risk-neutral shareholders, indexed by b. Each shareholder is endowed with $e > 0$ shares. There is a proposal on which shareholders vote. The proposal can be either accepted ($d = 1$) or rejected ($d = 0$). Each share has one vote. If a proportion of more than $\tau \in (0,1)$ of all shares are cast in favor of the proposal, the proposal is accepted. Otherwise, the proposal is rejected.[11]

Shareholders differ in their preferences regarding the proposal. The value of a share from the perspective of shareholder indexed by b depends on the state $\theta \in \{-1, 1\}$, on whether or not the proposal is accepted $d \in \{0, 1\}$, and on the shareholder's bias b:

$$v(d, \theta, b) = v_0 + (\theta + b)(d - \phi), \tag{1}$$

where $v_0 \geq 0$ is sufficiently large to ensure that shareholder value is non-negative under all circumstances. The state θ captures the part of value that is common to all shareholders: They are all more willing to accept the proposal if it is expected to increase value (i.e., $\theta = 1$ is more likely). However, due to different attitudes toward the proposal, shareholders apply different hurdle rates for accepting it. Specifically, shareholder b would like the proposal to be accepted if and only if his expectation of $\theta + b$ is positive. Parameter b, which can be positive or negative, measures the shareholder's bias b toward proposal approval. We will refer to low (high) b as "conservatism" ("activism"). Differences in shareholders' preferences can stem from private benefits, different social or political views, time horizons, risk aversion, or tax considerations. As noted in the introduction, the evidence for preference heterogeneity is prevalent. The initial shareholder base, i.e., the cross section of shareholders' biases b, is given by a differentiable cdf G, which is publicly known and has full support with positive density g on $\left[-\bar{b}, \bar{b}\right]$, where $\bar{b} > 0$ measures the heterogeneity among shareholders.

Parameter ϕ governs the relationship between the shareholder's attitude toward the pro-

---

[11]There is heterogeneity across companies with respect to the majority requirement used in shareholder voting. While a large fraction of companies use a simple majority rule, many companies still have supermajority voting for issues such as mergers or bylaw and charter amendments, and supermajority requirements are often a subject of debate (See Papadopoulos (2019) and Maug and Rydqvist (2009)).

posal (i.e., bias b) and his valuation of the firm. The shareholder's valuation of the firm "as is" is $v(0, \theta, b) = v_0 - (\theta + b)\phi$, and his valuation under the new strategy is $v(1, \theta, b) = v_0 + (\theta + b)(1 - \phi)$. The added value of the proposal, defined as $v(1, \theta, b) - v(0, \theta, b)$, is equal to $\theta + b$. If $\phi < 0$ ($\phi > 1$), then activist shareholders value the firm more (less) than conservative shareholders regardless of whether or not the proposal is accepted, that is, both $v(1, \theta, b)$ and $v(0, \theta, b)$ increase (decrease) in b. However, if $\phi \in (0, 1)$, then activist shareholders value the firm more than conservative shareholders if and only if the proposal is sufficiently likely to be accepted. In those cases, the relationship between the shareholder's attitude toward the proposal and his valuation of the firm depends on the expectation of d, so the expected voting outcome is critical for whether activist or conservative shareholders value the firm more.

To illustrate the role of the heterogeneity parameter b, suppose b captures variation among shareholders' time horizons, where a larger b reflects a shorter horizon, i.e., more impatience. Suppose also that shareholders vote on a proposal that will shorten the horizon of the firm's projects (e.g., by inducing management to cut R&D). Then $\phi < 0$ corresponds to the situation when the existing projects of the firm are already very short-term, and thus impatient shareholders (i.e., activists) value the firm relatively more even if the proposal is rejected. The case $\phi > 1$ corresponds to the opposite situation when the existing projects of the firm are very long-term, and thus patient shareholders (i.e., conservatives) value the firm relatively more even if the proposal is approved. Finally, $\phi \in (0, 1)$ corresponds to the situation when the horizon of the firm's existing projects is more balanced, and thus the relative effect of the proposal on shareholders' valuations is more significant: impatient shareholders value the firm relatively more if and only if the proposal is likely to be accepted. The role of ϕ will become clearer below, when we characterize the equilibria of the game.

The game has two stages: first, trading and then, voting. At the outset, all shareholders are uninformed about the value of θ; they all have the same prior on its distribution, which we specify below. Then trading takes place. Short sales are not allowed. In the baseline model, shareholders can either sell any amount of shares up to their entire endowment e, or buy any amount of shares up to a fixed quantity $x > 0$, or not trade. The quantity x captures trading frictions (e.g., illiquidity, transaction costs, wealth constraints), which limit

shareholders' ability to build large positions in the firm. In the Online Appendix, we consider the case in which trading frictions also limit shareholders' ability to sell their entire endowment e; our main results continue to hold for this case. In equilibrium the market must clear, and we denote the market clearing share price by p. To ease the notation in the analysis below, we define

$$\lambda \equiv \frac{x}{x + e}, \tag{2}$$

which captures the relative strength with which shareholders can buy shares. We interpret λ as market liquidity, in particular, as market depth. We assume that shareholders do not trade if they are indifferent between trading at the market price p and not trading at all. This tie-breaking rule could be rationalized by adding arbitrarily small transaction costs to the model.[12]

After the market clears, but before voting takes place, all shareholders observe a public signal about the state θ. This public information may stem from disclosures by management, analysts, or proxy advisors. Let $q = \mathbb{E}[\theta|\text{public signal}]$ be the shareholders' posterior expectation of the state following the signal. For simplicity and ease of exposition, we assume that the public signal is q itself, and that q is distributed according to a differentiable cdf F with mean zero and full support with positive density f on $[-\Delta, \Delta]$, where $\Delta \in (0, 1)$. Thus, the ex-ante expectation of θ is zero. The symmetry of the support of q around zero is not necessary for any of the main results. To simplify the exposition, it is useful to introduce

$$H(q) \equiv 1 - F(q). \tag{3}$$

At the second stage, after observing the public signal q, each shareholder votes the shares he owns after the trading stage, based on his preferences and the realization of q. Shareholders vote either in favor or against the proposal (no abstentions). Hence, we assume that the record date, which determines who is eligible to participate in the vote, is after the trading stage.[13]

---

[12]The purpose of this tie-breaking rule is to exclude equilibria that exist only in knife-edge cases. However, as the proof of Proposition 3 shows, other tie-breaking rules also eliminate these knife-edge equilibria — for example, rules under which indifferent shareholders always sell or always buy shares.

[13]If the record date were set prior to the trading stage, then shareholders who had sold their shares could still vote. We do not analyze such "empty voting."

We analyze subgame perfect Nash equilibria in undominated strategies of the induced voting game. The restriction to undominated strategies is common in voting games, which typically impose the equivalent restriction that agents vote as-if-pivotal.[14] This restriction implies that shareholder b votes his shares in favor of the proposal if and only if $b + q > 0$.

4   Analysis

We solve the model by backward induction. Before analyzing the full model with trading and voting, we first analyze two benchmark cases to build the intuition for this model, one in which shareholders vote but do not trade (Section 4.1) and one in which they trade but do not vote (Section 4.2).

We start by showing that regardless of trading, proposal approval at the voting stage takes the form of a simple cutoff rule:

Lemma 1. *If the proposal is decided by a shareholder vote, then in any equilibrium, there exists q^* such that the proposal is approved by shareholders if and only if $q > q^*$.*

Intuitively, this result follows because all shareholders, regardless of their biases, value the proposal more if it is more likely to increase value, i.e., if $\theta = 1$ is more likely.

4.1   Voting without trading

To begin, we develop the benchmark case in which shareholders vote but do not trade. Lemma 1 also applies in this case. The shareholder base at the voting stage is characterized by the pre-trade distribution G, and the proposal is approved if and only if at least fraction τ of the initial set of shareholders vote in favor. Since shareholders with a larger bias value the proposal more, it is approved if and only if the $(1 - \tau)$-th shareholder, who has a bias of $G^{-1}(1 - \tau)$, votes for the proposal. Hence, the cutoff q^* is given by the expression in Proposition 1:

---

[14]See, e.g., Baron and Ferejohn (1989) and Austen-Smith and Banks (1996). This restriction helps rule out trivial equilibria, in which shareholders are indifferent between voting for and against because they are never pivotal.

Proposition 1 (voting without trading). *If the proposal is decided by a shareholder vote but trading is not allowed, there always exists a unique equilibrium. In this equilibrium, the proposal is approved by shareholders if and only if $q > q_{NoTrade}$, where*

$$q_{NoTrade} \equiv -G^{-1}(1-\tau).$$
(4)

Figure 1 illustrates the equilibrium of Proposition 1 and plots the cdf G against the private values (biases) b. The shareholder with a bias $b = -q_{NoTrade}$ is the *marginal voter*, whose vote on the proposal determines whether it is approved. We will use the term "marginal voter" throughout the paper: The identity of this shareholder is crucial for the decision on the proposal. If $q = q_{NoTrade}$, there are $G(-q_{NoTrade}) = 1 - \tau$ shareholders for whom $b + q < 0$, who vote against ("Reject" region of the figure), and τ shareholders who vote in favor of the proposal ("Accept" region). Thus, the marginal voter is the shareholder who is indifferent between accepting and rejecting the proposal if exactly τ shareholders vote to accept it.

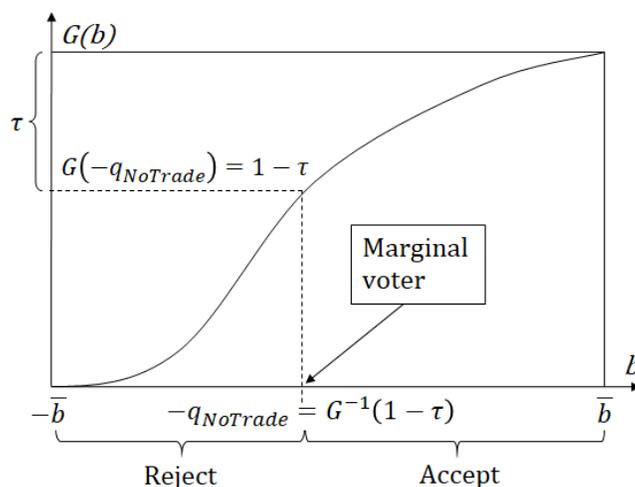

Figure 1 - Equilibrium characterization of the No-trade benchmark

4.2 Trading without voting

In the next step, we consider the second, complementary benchmark case, in which we have trading without voting. In this case, trading occurs as in the general model but then, after

13

the public signal q is revealed, the decision on the proposal is made by an exogenous agent. For concreteness, and to prepare for our later discussion of delegation in Section 6, we assume that the decision is made by the board of directors. We abstract from collective decision-making within the board and treat it as one single agent who acts like a shareholder with bias $b_m \in [-\bar{b}, \bar{b}]$ and valuation $v(d, \theta, b_m)$, so that it approves the proposal if and only if $b_m + q > 0$. Motivated by Lemma 1, we cast the following discussion in terms of a general exogenous decision rule q^*; for the decision rule of the board we have $q^* = -b_m$.

Denote by $v(b, q^*)$ the valuation of a shareholder with bias b, prior to the realization of q, as a function of the cutoff q^*. When trading, the shareholder optimally buys x shares if his valuation exceeds the market price, $v(b, q^*) > p$, sells his endowment of e shares if $v(b, q^*) < p$, and does not trade otherwise. Then

$$v(b, q^*) = \mathbb{E}\left[v\left(\mathbf{1}_{q > q^*}, \theta, b\right)\right],\tag{5}$$

where $\mathbf{1}_{q > q^*}$ is the indicator function that obtains a value of one if $q > q^*$ and zero otherwise, and $v(d, \theta, b)$ is defined by (1). Notice that $v(b, q^*)$ can be rewritten as

$$v(b, q^*) = v_0 + b\left(H(q^*) - \phi\right) + H(q^*)\,\mathbb{E}\left[\theta | q > q^*\right],\tag{6}$$

and that $v(b, q^*)$ increases in b if and only if $H(q^*) > \phi$. In words, activist shareholders with a large bias toward the proposal value the firm more than conservative shareholders with a small bias if and only if the proposal is sufficiently likely to be approved. This observation will play a key role in the analysis below.

Proposition 2 (trading without voting). *There always exists a unique equilibrium of the game in which the proposal is decided by a board with decision rule q^*.*

(*i*) *If $H(q^*) > \phi$, the equilibrium is "**activist:**" a shareholder with bias b buys x shares if $b > b_a$ and sells his entire endowment e if $b < b_a$, where*

$$b_a \equiv G^{-1}(\lambda).\tag{7}$$

14

The share price is given by $p = v(b_a, q^*)$.

(ii) *If $H(q^*) < \phi$, the equilibrium is "**conservative**:" a shareholder with bias b buys x shares if $b < b_c$ and sells his entire endowment e if $b > b_c$, where*

$$b_c \equiv G^{-1}(1 - \lambda). \tag{8}$$

The share price is given by $p = v(b_c, q^*)$.

(iii) *If $H(q^*) = \phi$, no shareholder trades and the price is $p = v_0 + \phi \mathbb{E}[\theta | q > q^*]$.*

In equilibrium, the firm is always owned by investors who value it most, which gives rise to two different types of equilibria. In part (i) of Proposition 2, the equilibrium is "activist" in the sense that activist shareholders buy shares from conservatives and the post-trade shareholder base has a high preference b for the proposal. In part (ii), the equilibrium is "conservative" in the sense that conservative shareholders buy from activists, creating a post-trade shareholder base that has a low preference b for the proposal.

What determines which type of shareholders value the firm the most? Critically, according to expression (6), shareholders' valuation $v(b, q^*)$ increases in b if and only if $H(q^*) > \phi$, where $H(q^*) = \Pr[q > q^*]$ is the probability that the proposal is expected to be approved. Thus, if the proposal is approved with a relatively high (low) probability, activist shareholders value the firm more (less), and in equilibrium they buy (sell) shares from (to) conservative shareholders. Parameter ϕ, which governs the relationship between the shareholder's attitude toward the proposal and his valuation of the firm, determines how high (low) the likelihood of the proposal's approval must be in order for activists (conservatives) to be the shareholders with the highest valuation.

In the activist (conservative) equilibrium the market-clearing condition determines the "marginal trader" with bias b_a (b_c). This trader is indifferent between buying and selling shares given the market price. In the activist equilibrium, the $1 - G(b_a)$ most activist shareholders with $b > b_a$ buy x shares each, whereas the remaining $G(b_a)$ more conservative shareholders sell e shares each. Hence, market clearing requires $x(1 - G(b_a)) = eG(b_a)$, or $G(b_a) = \lambda$ from

(2), which gives the marginal trader b_a as in (7). The equilibrium share price $v(b_a, q^*)$ is thus determined by the identity of the marginal trader and equals his valuation of the firm, which depends on the board's decision rule q^*. This equilibrium is illustrated in the left panel of Figure 2, which shows the location of the marginal trader who is indifferent between buying and selling.

The conservative equilibrium is analogous to the activist equilibrium, except that now the $1 - G(b_c)$ most activist shareholders sell their e shares to the $G(b_c)$ most conservative shareholders, which implies $G(b_c) = 1 - \lambda$ by the same reasoning as for the activist equilibrium. It is displayed in the right panel of Figure 2. In what follows, we ignore the knife-edge case (iii), in which $H(q^*) = \phi$ and no shareholder trades.[15] Finally, we note that the equilibrium is unique, i.e., there is no set of parameters for which the conservative equilibrium and the activist equilibrium can coexist.

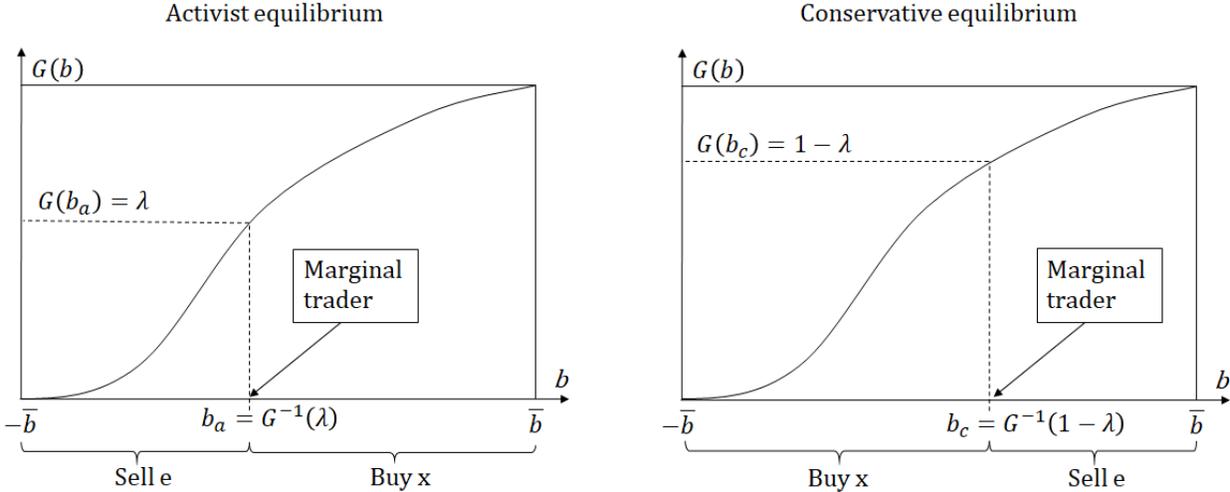

Figure 2 - Equilibrium characterization of the No-vote benchmark

The identity of the marginal trader depends on the trading frictions, as summarized in the next result.

Corollary 1. *The marginal trader becomes more extreme when trading frictions are relaxed,*

---

[15]In Section 4.3 we show that when trade is allowed, this knife-edge equilibrium does not exist.

i.e., b_c decreases in λ and b_a increases in λ. In addition, $b_c < b_a$ if and only if $\lambda > 0.5$.

Corollary 1 follows directly from expressions (7) and (8). To see the intuition, notice that when trading frictions are small (λ is large), shareholders with the strongest preference for the likely outcome, i.e., those with a large bias in the activist equilibrium and those with a small bias in the conservative equilibrium, have the highest willingness to pay and buy the maximum number of shares. We sometimes refer to these shareholders as "extremists." Other shareholders with more moderate views (i.e., $b \in (b_c, b_a)$), take advantage of this opportunity and sell their shares to shareholders with extreme views. In contrast, when trading frictions are large (λ is small), only shareholders with the most extreme view *against* the likely outcome find it beneficial to sell their shares at a low price, while moderate shareholders (i.e., $b \in (b_a, b_c)$) always buy shares. This explains why the marginal trader in an activist equilibrium is more activist than in the conservative equilibrium if and only if trading frictions are relatively small ($\lambda > 0.5$).

Overall, when trading frictions are small, the post-trade ownership structure is dominated by extremists, who can translate their strong views on the proposal into large positions in the firm. In contrast, when trading frictions are large, the post-trade shareholder base is relatively moderate and closer to the initial shareholder base. Below we show that this feature of the model has significant implications for prices and welfare when the decision on the proposal is made by a shareholder vote.

4.3   Equilibrium with trading and voting

We now analyze the general model, in which shareholders trade their shares, and those who own the shares after the trading stage vote those shares at the voting stage. We first characterize the equilibria and discuss their properties (Section 4.3.1). Then we discuss the complementarity between trading and voting and derive the circumstances under which multiple equilibria exist (Section 4.3.2).

4.3.1 Existence and characterization of equilibria

According to Lemma 1, the decision rule on the proposal takes the form of an endogenous cutoff q^*, and the proposal is approved if and only if $q > q^*$, i.e., with probability $H(q^*)$. The value of the firm for shareholder b as a function of q^* is again given by (6). As in the no-vote benchmark, $v(b, q^*)$ is increasing in b if and only if $H(q^*) > \phi$. At the trading stage, a shareholder with bias b buys x shares if $v(b, q^*) > p$, sells his endowment of e shares if $v(b, q^*) < p$, and does not trade otherwise. However, differently from the no-vote benchmark, the decision rule is now tightly linked to the trading outcome. In particular, the trading stage determines the composition of the shareholder base at the voting stage, which, in turn, determines the cutoff q^* and the probability that the proposal is approved. Therefore, there is a feedback loop between trading and voting: Shareholders' trading decisions depend on expected voting outcomes, and voting outcomes depend on how trading changes the shareholder base. The next result fully characterizes the equilibria of the game.

Proposition 3 (trading and voting). *An equilibrium of the game with trading and voting always exists.*

(i) *An **activist** equilibrium exists if and only if $H(q_a) > \phi$, where*

$$q_a \equiv -G^{-1}(1 - \tau(1 - \lambda)). \tag{9}$$

In this equilibrium, a shareholder with bias b buys x shares if $b > b_a$ and sells his entire endowment e if $b < b_a$, where $b_a \equiv G^{-1}(\lambda)$. The proposal is accepted if and only if $q > q_a$, and the share price is given by $p_a = v(b_a, q_a)$.

(ii) *A **conservative** equilibrium exists if and only if $H(q_c) < \phi$, where*

$$q_c \equiv -G^{-1}((1 - \lambda)(1 - \tau)). \tag{10}$$

In this equilibrium, a shareholder with bias b buys x shares if $b < b_c$ and sells his entire endowment e if $b > b_c$, where $b_c = G^{-1}(1 - \lambda)$. The proposal is accepted if and only if

18

$q > q_c$, and the share price is given by $p_c = v(b_c, q_c)$.

(*iii*) *Other equilibria do not exist.*

Note that $q_c > q_a$: the cutoff for accepting the proposal is higher in the conservative equilibrium than in the activist equilibrium. Accordingly, the probability of accepting the proposal is higher in the activist equilibrium, i.e., $H(q_a) > H(q_c)$. Figure 3 illustrates both equilibria and combines the respective elements from Figures 1 and 2.

The logic behind both equilibria is the same as in the no-vote benchmark in Proposition 2. In the activist equilibrium displayed in the left panel of Figure 3, the cutoff q_a is relatively low ($-q_a$, the bias of the marginal voter, is high) and the proposal is likely to be approved. Hence, the term $H(q_a) - \phi$ in (6) is positive, so conservative shareholders who are biased against the proposal, $b < b_a$, sell their endowment to shareholders who are biased toward the proposal, $b > b_a$. The marginal trader b_a is determined by the exact same market clearing condition described in Proposition 2. Hence, $1 - G(b_a) = 1 - \lambda$ shareholders own the firm after trading, and of these, at least $\tau(1 - \lambda)$ need to approve the proposal to satisfy the majority requirement, so that $1 - G(-q_a)$ shareholders vote in favor, with q_a defined by (9). Importantly, and differently from the no-vote benchmark, the cutoff q_a is now *endogenously* low: the fact that the post-trade shareholder base consists of shareholders who are biased toward the proposal, $b > b_a$, implies that the post-trade shareholders will optimally vote in favor of the proposal unless their expectation q is sufficiently low to offset their bias. Hence, the expectations about the high likelihood of proposal approval become self-fulfilling.

Similarly, in the conservative equilibrium displayed in the right panel of Figure 3, shareholders expect a low probability of approval (i.e., q_c is high). Hence, the term $H(q_c) - \phi$ in (6) is negative, and shareholders with $b < b_c$ value the firm more and buy shares from shareholders with $b > b_c$. Since the post-trade shareholder base consists of shareholders who are biased against the proposal and are more likely to reject it, expectations about the low probability of approval are self-fulfilling.
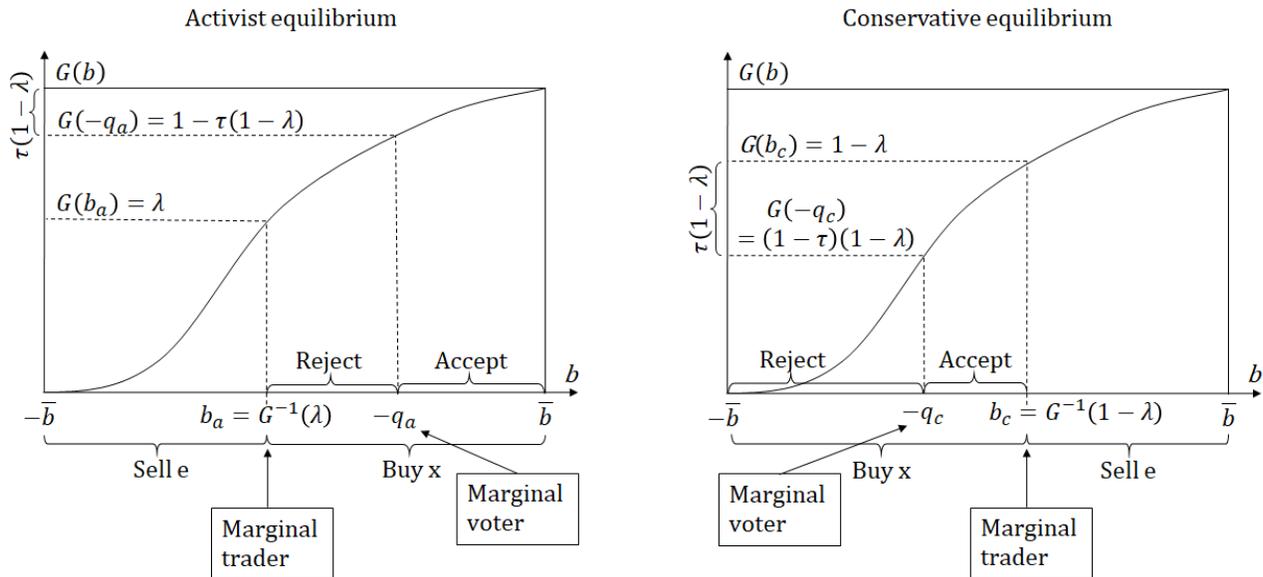

Figure 3 - Equilibrium characterization of the model with trading and voting

Figure 3 also shows that the marginal voter is always more extreme than the marginal trader, i.e., in the activist (conservative) equilibrium, the marginal voter is more activist (conservative) than the marginal trader: $-q_a > b_a$ $(-q_c < b_c)$. These relationships, which play a key role in the analysis of welfare and prices in Section 5, can be easily verified from the expressions in Proposition 3.

Similar to Lemma 1 in the no-vote benchmark, the marginal trader becomes more extreme when trading frictions are relaxed, i.e., b_a (b_c) increases (decreases) in λ. In addition, it follows from the expressions (9) and (10) that $-q_a$ $(-q_c)$ increases (decreases) in λ. Thus, both the marginal trader and the marginal voter become more extreme as trading frictions are relaxed. However, the extreme to which they converge as trading frictions disappear depends on the type of equilibrium, that is, whether it is activist or conservative:

Corollary 2. *The marginal voter becomes more extreme when trading frictions are relaxed. In the activist (conservative) equilibrium, $-q_a$ increases in λ, and $-q_a$ and b_a both converge to $\bar{b}$ as $\lambda \to 1$ ($-q_c$ decreases in λ, and $-q_c$ and b_c both converge to $-\bar{b}$ as $\lambda \to 1$).*

20

The intuition is similar to the intuition of the no-vote benchmark: When trading frictions are relaxed, the post-trade shareholder base is dominated by extremists who hold larger positions in the firm, whereas the more moderate shareholders sell. The more extreme preferences of the post-trade shareholder base then push the firm's decision-making to the extreme. This analysis uncovers a new effect of liquidity on governance through voice: Higher liquidity makes the firm's decision rule more extreme and increases the turnover of the shareholder base before important decisions.

4.3.2   Multiple equilibria

As the above discussion shows, the introduction of the voting stage creates self-fulfilling expectations: Shareholders with a preference for the expected outcome buy shares, which in turn makes their preferred outcome more likely. Voting also creates strategic complementarities at the trading stage between agents with similar preferences. For example, if an activist shareholder with a large bias towards the proposal is more likely to buy shares and, therefore, more likely to vote for the proposal, this increases the likelihood of proposal acceptance and hence the payoff from buying for another activist shareholder. This complementarity, and the presence of self-fulfilling expectations, suggest that the two equilibria—conservative and activist—can coexist. Indeed, according to Proposition 3, both equilibria exist whenever

$$H(q_c) < \phi < H(q_a). \tag{11}$$

The multiplicity of equilibria can be interpreted as an additional source of volatility if agents change expectations for exogenous reasons.[16] Hence, without any change in the fundamentals

---

[16]Some researchers treat multiple equilibria as a modeling problem and suggest modeling strategies that restore uniqueness. For example, Morris and Shin (2000) attribute multiplicity of equilibria to the unrealistic assumptions that fundamentals are common knowledge and that agents make correct predictions about each others' behavior with certainty (see also Morris and Shin (2003) for a more extensive discussion of the global games literature). However, theoretical results as well as experimental observations suggest that the multiplicity of equilibria may be genuine, which poses the question of how agents coordinate on an equilibrium and how they form expectations about which equilibrium will prevail. Indeed, Angeletos and Werning (2006) show that multiple equilibria obtain even if agents have only noisy information about each others' behavior if the common information is generated endogenously in a financial market, which contradicts the claim of Morris and Shin (2000) that multiplicity obtains only if agents have perfect information of others' behavior. Heinemann, Nagel, and Ockenfels (2004) perform experiments that also cast doubt on the same claim by showing that whether

---

of the firm, prices and voting outcomes may change if agents form different expectations and, accordingly, coordinate on a different equilibrium. Therefore, we treat multiple equilibria as a source of non-fundamental uncertainty or indeterminacy. The indeterminacy associated with multiple equilibria also underscores potential empirical challenges in analyzing shareholder voting and could explain the mixed evidence about the effect of voting on proposals on shareholder value.[17] The same proposal voted on at two firms with similar characteristics and fundamentals could have very different voting outcomes and valuation effects. In this respect, multiplicity of equilibria sheds a different perspective on empirical findings.

The next result highlights the factors that contribute to the multiplicity of equilibria.

Proposition 4. *The conservative and the activist equilibria coexist if the market is liquid (sufficiently high λ); if the voting requirement is in an intermediate interval, $\tau \in (\underline{\tau}, \overline{\tau})$; if the expected voting outcome is critical for whether activist or conservative shareholders value the firm more, $\phi \in (H(q_c), H(q_a))$; and only if heterogeneity of the initial shareholder base is large (sufficiently large $\overline{b}$).*

Intuitively, the multiplicity of equilibria arises from the possibility that expectations become self-fulfilling. If shareholders can take larger positions, i.e., λ is large, then extreme shareholders accumulate larger positions in the firm. The firm experiences larger shifts in the shareholder base, and the direction of these shifts depends on shareholders' expectations about the proposal outcome. As the post-trade shareholder base and the marginal voter in each equilibrium become more extreme, the interval in (11) in which the two equilibria coexist expands, so that (11) is more easily satisfied. Conversely, for small λ, i.e., large trading frictions, both types of equilibria converge to the no-trade benchmark as $\lambda \rightarrow 0$ ($q_a \rightarrow q_{NoTrade}$ and $q_c \rightarrow q_{NoTrade}$), so the interval in (11) in which multiple equilibria exist vanishes.

Multiple equilibria are also less likely to exist if the governance structure requires either very large or very small majorities to approve a decision: If τ is sufficiently large (small),

then an activist (conservative) equilibrium is unlikely to exist because approval of the proposal requires almost all shareholders to vote in its favor (against). Since most firms have simple majority voting rules, the non-fundamental indeterminacy we point out seems important.

Activist and conservative equilibria are more likely to coexist if ϕ is neither too large nor too small. That is, the effect of the proposal's approval must be critical for whether activist or conservative shareholders value the firm more. If ϕ is too large (too small), then the activist (conservative) shareholders value the firm less regardless of the expected decision and have low incentives to buy. Hence, the shareholder base does not shift toward activist (conservative) shareholders, so the activist (conservative) equilibrium cannot exist, and multiplicity vanishes.

Finally, the heterogeneity among shareholders has to be sufficiently large, since only then are there enough shareholders with extreme views or preferences regarding the proposal who can give rise to both types of equilibria.

5   Welfare and prices

In this section we analyze the welfare and price effects of trading and voting. We start by deriving general properties that form the basis for our discussion. We then show that shareholder welfare and prices may move in opposite directions in response to changes in parameters (Section 5.1), and then show that greater opportunities to trade can be detrimental for both prices and welfare (Section 5.2).

The equilibrium share price is characterized by Proposition 3, which shows that the price depends on the identities of the marginal voter and the marginal trader, $p_a = v(b_a, q_a)$ and $p_c = v(b_c, q_c)$. The marginal voter determines the firm's decision rule regarding the proposal, and the marginal trader's valuation given this decision rule determines the market price.

We now derive the aggregate expected welfare of all shareholders (hereafter, expected welfare). In the activist equilibrium, whenever it exists, the expected welfare is

$$W_a = ep_a \Pr[b < b_a] + \mathbb{E}[(e+x)v(b, q_a) - xp_a | b > b_a] \Pr[b > b_a]. \qquad (12)$$

Similarly, in the conservative equilibrium, the expected welfare is

$$W_c = ep_c \Pr\left[b > b_c\right] + \mathbb{E}\left[(e + x)\,v\left(b, q_c\right) - xp_c|b < b_c\right]\Pr\left[b < b_c\right]. \tag{13}$$

In both expressions, the first term captures the value of shareholders who sell their endowment e in equilibrium, whereas the second term is the expected value of shareholders who buy shares in equilibrium: it equals the value of their post-trade stake in the firm minus the price paid for the additional shares acquired through trading. To simplify the notations, we define

$$\beta_a \equiv \mathbb{E}\left[b|b > b_a\right] \text{ and } \beta_c \equiv \mathbb{E}\left[b|b < b_c\right], \tag{14}$$

which denotes the average bias of the post-trade shareholder base for, respectively, the activist and the conservative equilibrium. The average bias of the post-trade shareholder base plays a critical role in the following welfare analysis. Indeed, while the share price is determined by the valuation of the *marginal* trader, the next result shows that the expected welfare is determined by the valuation of the *average* post-trade shareholder.

Lemma 2. *In any equilibrium, the expected welfare of the shareholder base pre-trade is equal to the valuation of the average post-trade shareholder. In particular,*

$$W_a = e \cdot v\left(\beta_a, q_a\right) \text{ and } W_c = e \cdot v\left(\beta_c, q_c\right). \tag{15}$$

To understand Lemma 2, notice first that the expected welfare of the pre-trade shareholder base equals the expected welfare of the shareholder base post-trade, $\mathbb{E}\left[v\left(b, q_a\right)|b > b_a\right]$ in the activist equilibrium and $\mathbb{E}\left[v\left(b, q_c\right)|b < b_c\right]$ in the conservative equilibrium. Intuitively, market clearing implies that all the gains of the shareholders who sell shares are offset by the losses of the shareholders who buy shares. Since selling shareholders sell their entire endowment, their valuations are fully captured by the transfers from buying shareholders. The linearity of $v\left(b, q^*\right)$ in b in turn implies that the expected welfare of the shareholder base post-trade is equal to the valuation of the average post-trade shareholder.

Before deriving the main results of this section, we analyze the conditions under which

the expected welfare and the share price are maximized. For this purpose, we consider the following thought experiment: Holding everything else equal, when does $v(b, q^*)$ obtain its maximum as a function of the marginal voter's bias $-q^*$? Expression (6) implies

$$\frac{\partial v(b, q^*)}{\partial q^*} > 0 \Leftrightarrow -q^* > b. \tag{16}$$

Therefore, the valuation $v(b, q^*)$ of a shareholder with bias b is maximized if $-q^* = b$, i.e., if the marginal voter, who determines the decision, represents the shareholder's view.

Since in the activist equilibrium $p_a = v(b_a, q_a)$ and $W_a = e \cdot v(\beta_a, q_a)$, and in the conservative equilibrium $p_c = v(b_c, q_c)$ and $W_c = e \cdot v(\beta_c, q_c)$, this insight gives the following result, which plays a central role in the analysis below.

Lemma 3.

(i) *The share price obtains its maximum when the bias of the marginal voter equals the bias of the marginal trader (b_a in the activist equilibrium and b_c in the conservative equilibrium).*

(ii) *The expected welfare obtains its maximum when the bias of the marginal voter equals the bias of the average post-trade shareholder (β_a in the activist equilibrium and β_c in the conservative equilibrium).*

By implication, the share price increases (decreases) if the marginal voter moves toward (away from) the position of the marginal trader. Similarly, welfare increases (decreases) if the marginal voter moves toward (away from) the position of the average post-trade shareholder. In the following subsections, we use these insights to explore the welfare and price effects.[18]

5.1 Opposing effects on welfare and prices

The literature in financial economics often draws a parallel between welfare and prices and uses stock returns to approximate effects on welfare. This parallel is natural if shareholders have

---

[18] In an empirical study of proxy contests, Listokin (2008) also observes the difference between the preferences of marginal traders, who set prices, and marginal voters, who determine voting outcomes, and concludes that marginal voters value management control more than marginal traders in his sample.

homogeneous preferences. The next result highlights that if shareholders have heterogeneous preferences, shareholder welfare and prices may in fact move in opposite directions in response to exogenous changes to the firm's governance structure or trading environment.

Proposition 5. *Suppose the marginal voter is less extreme than the average post-trade shareholder (i.e., $-q_a < \beta_a$ in the activist equilibrium and $-q_c > \beta_c$ in the conservative equilibrium), and consider a small exogenous change in parameters that affects the position of the marginal voter without affecting the marginal trader or the average post-trade shareholder. Then, if such a change in parameters increases (decreases) shareholder welfare, it also necessarily decreases (increases) the share price.*

To explain the intuition behind the opposing effects on shareholder welfare and the share price, we focus on the activist equilibrium. (The intuition for the conservative equilibrium is similar.) Recall that the share price is the valuation of the marginal trader b_a, whereas shareholder welfare is the valuation of the average post-trade shareholder, β_a. As long as trade is not frictionless (i.e., $\lambda < 1$), the average post-trade shareholder is more extreme than the marginal trader ($\beta_a > b_a$), and as a result, there is a wedge between shareholder welfare and the share price. Recall also that the marginal voter is always more extreme than the marginal trader, i.e., $-q_a > b_a$. Hence, if the marginal voter is less extreme than the average post-trade shareholder, then $b_a < -q_a < \beta_a$, and hence any small exogenous change to q_a that does not affect β_a or b_a either increases the distance of $-q_a$ from b_a and decreases the distance of $-q_a$ from β_a, or the other way around. As shown in (16) and Lemma 3 above, the key determinant of the price (welfare) is the distance between the marginal trader b_a (average post-trade shareholder β_a) and the marginal voter $-q_a$. Thus, such a change in the identity of the marginal voter necessarily has opposite effects on prices and welfare.

An exogenous change to the majority requirement τ is an example of a parameter change in our setting that affects the marginal voter without affecting the position of the marginal trader or the average post-trade shareholder, as required by Proposition 5.

Corollary 3. *Suppose in equilibrium the marginal voter is less extreme than the average post-trade shareholder. Then, a small change in the majority requirement τ that increases*

(decreases) shareholder welfare, necessarily decreases (increases) the share price.

Indeed, based on expressions (9) and (10) in Proposition 3, an increase in τ implies that the marginal voter becomes more conservative in both equilibria (i.e., $-q_a$ and $-q_c$ decrease in τ). This is because an increase in τ requires shareholders with a lower preference for the proposal to vote in favor. At the same time, τ has no effect on the marginal trader (b_a and b_c), and hence, on the average post-trade shareholder (β_a and β_c). Corollary 3 is then a direct consequence of Proposition 5. Proposition 9 in the Online Appendix characterizes the majority requirement that maximizes the expected shareholder welfare. In general, the optimal majority requirement will not be a simple majority, and it will depend on trading frictions λ.

Importantly, the opposing welfare and price effects are not unique to changes in the majority requirement or, more generally, to parameters that only affect the identity of the marginal voter: any parameter shift that moves the marginal voter closer to the marginal trader but farther from the average post-trade shareholder will have opposing effects on welfare and prices.

Overall, Proposition 5 highlights a potential limitation to prices as a measure of shareholder welfare in the context of shareholder voting. By using prices as a proxy for welfare, the researcher may sometimes not only obtain a biased estimate of the real effect of the proposal, but even get the wrong sign of the effect.

5.2   Trading frictions

Trade in our model enables shareholders with different views and preferences to exchange shares with each other in order to improve their welfare. In particular, larger opportunities to trade allow shareholders to build larger positions, so that the post-trade ownership structure becomes more concentrated among the most extreme shareholders. Therefore, when decisions on the proposal are not themselves affected by trade, e.g., when the decision is made by the board as in the no-vote benchmark of Section 4.2, the ability to trade always increases the share price and shareholder welfare:

Lemma 4. *When the proposal is decided by a board with decision rule q^*, the share price and the expected welfare increase when trading frictions are relaxed (i.e., larger λ).*

By contrast, the next result demonstrates that when shareholders vote, then greater opportunities to trade can in fact reduce the share price and expected welfare.

Proposition 6. *Suppose the proposal is decided by a shareholder vote and $|q_{NoTrade}| < \Delta$. There exist $\underline{\lambda}$ and $\overline{\lambda}$, $0 < \underline{\lambda} < \overline{\lambda} < 1$, such that in any equilibrium:*

(i) *The share price increases in λ if $\lambda > \overline{\lambda}$, and decreases in λ if $\lambda < \underline{\lambda}$ and $|H(q_{NoTrade}) - \phi|$ is sufficiently small.*

(ii) *The expected welfare increases in λ if $\lambda > \overline{\lambda}$, and decreases in λ if $\lambda < \underline{\lambda}$, $|H(q_{NoTrade}) - \phi|$ is sufficiently small, and the marginal voter in this equilibrium is more extreme than the average post-trade shareholder.*

Consider first the price effect in part (i). From Proposition 3, the share price reflects the valuation of the marginal trader, which depends on the decision of the marginal voter. Since the marginal trader is always less extreme than the marginal voter, the voting outcome is never optimal from his point of view, since shareholders in the activist (conservative) equilibrium vote in favor of (against) the proposal too often. The stock price increases with liquidity if and only if the distance between the marginal trader and the marginal voter declines. When liquidity λ is large, then increasing it further implies that both, the marginal trader and the marginal voter, converge to the most extreme shareholder, and since the wedge between them shrinks to zero, the share price necessarily increases in λ. This explains the cutoff $\overline{\lambda}$.

In the opposite case, if λ is small and close to zero, the wedge between the marginal trader and the marginal voter can be large. For example, in the activist equilibrium, $\lim_{\lambda \to 0} b_a = -\overline{b}$, while $\lim_{\lambda \to 0} q_a = q_{NoTrade}$. Based on expression (6), $|H(q^*) - \phi|$ is the sensitivity of the shareholder's valuation to his attitude b towards the proposal. Thus, when this sensitivity is small, the marginal voter becomes extreme at a faster rate than the marginal trader as λ increases,[19] and as a result, the share prices decreases as liquidity increases. Overall, this result highlights that more trading opportunities can be detrimental to the share price because

---

[19]The condition $|q_{NoTrade}| < \Delta$ ensures that the marginal voter changes with λ when λ is small. Intuitively, this condition means that in the no-trade benchmark, the outcome of the vote is uncertain.

they make the marginal voter relatively more extreme and thereby decrease the value of the marginal trader.

The intuition behind the effect of λ on welfare in part (ii) is similar, with one exception. Recall that the key difference between welfare and the share price is that the former is the valuation of the average post-trade shareholder, while the latter is the valuation of the marginal trader. Whereas the marginal voter is always more extreme than the marginal trader, he is not necessarily more extreme than the average post-trade shareholder. Thus, relative to the conditions in part (i) for prices, the negative effect of trading opportunities λ on welfare also requires the marginal voter to be more extreme than the average post-trade shareholder—only in those circumstances can the wedge between the marginal voter and the average shareholder increase.[20]

Proposition 6 reveals a new force through which financial markets have real effects, which could be detrimental. In our setting financial markets do not aggregate or transmit investors' information to decision-makers. Instead, financial markets affect the ability of shareholders to accumulate large positions in the firm and then use their votes to impose their views. This effect can be detrimental to the ex-ante shareholder value, both to those shareholders who buy shares and to those who sell their shares in equilibrium. Intuitively, if more trade makes the marginal voter too extreme, then even shareholders who buy shares are worse off if their bias is moderate. Since the willingness to pay of these shareholders decreases, the price at which shareholders can sell their shares decreases as well. Therefore, both shareholders who sell their shares and the moderate shareholders who buy shares may be worse off if λ is higher. Only the most extreme shareholders are always better off when trading frictions are relaxed.[21]

---

[20]Note that the conditions in Proposition 5, which are necessary to obtain opposing effects on welfare and prices, require the marginal voter to be *less* extreme than the average post-trade shareholder. Thus, these conditions are violated by the assumptions of Proposition 6 part (ii), which require the marginal voter to be *more* extreme.

[21]Shareholders who are more extreme than the marginal voter (i.e., $b < -q_c$ in the conservative equilibrium and $b > -q_a$ in the activist equilibrium) benefit from a larger λ. This is because the marginal voter always becomes more extreme as λ increases, and hence his preferences become more aligned with these extreme shareholders.

6 Delegation

As shown in the previous section, when decisions are made by a shareholder vote, shareholders with extreme views can accumulate large positions and then use their voting power to impose their views on more moderate shareholders, which can be detrimental to aggregate welfare. This raises the question of whether shareholders would be better off if decision-making were instead delegated to the company's board of directors.

6.1 Optimal board

To study this question, we return to the game from Section 4.2 in which the decision is made unilaterally by a board of directors with bias b_m and decision rule $q^* = -b_m$, which approves the proposal with probability $H(-b_m)$.[22] As shown in Proposition 2, the equilibrium is unique and either activist, if the board is biased toward the proposal, or conservative, if it is biased against the proposal. Lemma 2 holds in this context as well, so the expected welfare of the initial shareholder base equals the expected welfare of the post-trade shareholder base, and is given by

$$W_{m,a} = e \cdot v\left(\beta_a, -b_m\right) \text{ and } W_{m,c} = e \cdot v\left(\beta_c, -b_m\right) \tag{17}$$

if the board is activist and conservative, respectively. We call the board optimal if it maximizes the expected shareholder welfare. The next result characterizes the bias of the optimal board and compares it to the welfare outcome with shareholder voting.

Proposition 7. *The bias of the optimal board and the expected welfare with the optimal board are given by*

$$b_m^* = \begin{cases} \beta_c & \text{if } v\left(\beta_c, -\beta_c\right) > v\left(\beta_a, -\beta_a\right) \\ \beta_a & \text{otherwise} \end{cases}, \quad W_m^* = e \cdot \max\left\{v\left(\beta_c, -\beta_c\right), v\left(\beta_a, -\beta_a\right)\right\}. \tag{18}$$

---

[22]Note that in our setting, the board has no informational advantage relative to shareholders when making its decision. Giving the board an informational advantage would increase the incentives of shareholders to delegate the decision on the proposal—an effect which has already been discussed in the existing literature.

(i) If $v(\beta_c, -\beta_c) < (>) v(\beta_a, -\beta_a)$, then the optimal board is more activist (conservative) than the average bias of the initial shareholder base, i.e., $b_m^* > \mathbb{E}[b]$ $(b_m^* < \mathbb{E}[b])$ and the induced delegation equilibrium is activist (conservative).

(ii) The expected welfare under the optimal board, W_m^*, is increasing in λ.

(iii) If the marginal voter in either equilibrium with shareholder voting is not given by b_m^* (i.e., $q_a \neq -b_m^*$ and $q_c \neq -b_m^*$), then there exists $\varepsilon > 0$ such that if $|b_m - b_m^*| < \varepsilon$, the induced delegation equilibrium generates a strictly higher expected welfare than any voting equilibrium.

The main implication of Proposition 7 is that it is optimal to have a biased board. According to part (i), the optimal board is always either more conservative or more activist relative to the initial shareholder base, i.e., $b_m^* \neq \mathbb{E}[b]$, even though it maximizes the welfare of the *initial* shareholder base. The intuition is similar to the one behind the welfare analysis in Section 5. Recall from Lemma 2 that the value of the selling shareholders is the price they receive for their shares, which is a transfer from the buying shareholders. Thus, the aggregate welfare of the initial shareholder base is exactly equal to the aggregate welfare of post-trade shareholders, which, in turn, is maximized by a biased board: The bias of the optimal board always equals the average bias of the *post-trade* shareholder base (β_a or β_c). Our prior analysis also implies that the optimal board is tightly linked to the firm's trading environment: As opportunities for trade (λ) increase, the post-trade shareholder base becomes more extreme, so the optimal board becomes more biased. The optimal board is unbiased only if there is no trading between shareholders, i.e., $b_m^* \to \mathbb{E}[b]$ as $\lambda \to 0$.

Overall, among all boards that induce an activist (conservative) equilibrium, the board that gives the highest shareholder welfare is one with a bias exactly equal to β_a (β_c). The optimal choice between an activist and a conservative board is determined by the welfare comparison of the activist and the conservative equilibria induced by these two boards.[23]

To see part (ii), recall that as λ increases, the post-trade shareholder base has more extreme preferences. Since the decisions of the optimal board are fully aligned with the preferences of

---

[23] In the Appendix we show that $v(\beta_c, -\beta_c) > v(\beta_a, -\beta_a)$ if and only if $\phi > \Phi$, where Φ is defined by (26).

the post-trade shareholders, a more extreme post-trade shareholder base values the firm more and welfare increases.

Finally, in part (iii), we compare the benefits from delegation to the board with decision-making via shareholder voting, which results in a decision rule q_a or q_c. We note that a board with bias $b_m = -q_a$ ($b_m = -q_c$) implements the outcome of the activist (conservative) voting equilibrium. Therefore, shareholders cannot be worse off with an optimally chosen board than with a shareholder vote. Moreover, shareholders are strictly better off with an optimal board except for the knife-edge cases in which the voting equilibrium already yields the highest expected welfare, i.e., if the marginal voter just happens to equal the post-trade average shareholder ($q_a = -b_m^*$ or $q_c = -b_m^*$). In all other cases, the board does not have to be optimal, but just has to be good enough in the sense of being in the interval around b_m^* to increase welfare relative to decision-making via voting. In the Online Appendix, we examine how the comparison between delegation to an optimal board and decision-making via shareholder voting depends on liquidity.

6.2 Voting to delegate to a board

Due to the heterogeneity of the shareholder base, even the optimal board, which maximizes the aggregate welfare of all shareholders, may nevertheless harm some of them. Those shareholders would prefer to retain their voting rights. This raises the question whether shareholders would delegate decision-making to a board that improves aggregate welfare, i.e., whether a fraction of at least τ of the initial shareholders would give up their right to vote on the proposal and leave the choice to the board. In other words, can we expect shareholders to reach a consensus on delegation?

To answer this question, in this section we analyze the following extension. Suppose that at the outset of the game, i.e., before the trading stage, shareholders choose between two alternatives: (i) all shareholders retain their voting rights, as in the baseline model; and (ii) all shareholders delegate decision-making authority to a board with an exogenously given bias b_m, which then decides on the proposal. Decision-making is delegated to the board only if at

least fraction τ of the shareholders supports it. Hence, we ask: Assuming the firm has a board with bias b_m, would at least τ of the initial shareholders ever vote in favor of surrendering their choice over the proposal to the board, rather than voting on the proposal themselves? Below, we show that the optimal board may not always be in the set of boards that can garner support from at least τ initial shareholders.

Proposition 8. *Suppose shareholders expect the activist (conservative) equilibrium in the voting game and the optimal board is activist (conservative) as well. Then, there exists $\overline{\tau} \in (0, 1)$ such that if $\tau \in (\overline{\tau}, 1)$, then at least $1-\tau$ initial shareholders strictly prefer retaining their voting rights over delegation to the optimal board.*

Hence, if τ is too high, shareholders will not delegate to the board, not even to the board that maximizes ex ante shareholder welfare. To see the intuition, consider the activist equilibrium (the intuition for the conservative equilibrium is similar). The initial shareholders' preferences over the board crucially depend on whether or not they plan to sell their stake in the firm. Indeed, shareholders who sell their shares ($b < b_a$) obtain a payoff proportional to the price p_a and hence would like to maximize the share price. Recall that the share price is given by the valuation of the marginal trader: $p_a = v(b_a, q^*)$, where q^* is the corresponding decision cutoff. From the marginal trader's perspective, delegation to a board with bias b_m is preferred to the conservative voting equilibrium whenever $b_m \in (b_a, -q_a)$, i.e., the board's position over the proposal is closer to his own position than that of the marginal voter. Therefore, all shareholders with $b < b_a$ would vote for a board with bias $b_m \in (b_a, -q_a)$. In contrast, consider shareholders with bias $b > b_a$, who buy shares. These shareholders have two reasons to prefer a board that is more activist than the marginal trader. First, because they are more activist than the marginal trader, they favor the proposal more and hence would intrinsically benefit from a more activist board. Second, because they pay $p_a = v(b_a, q^*)$ for each share they buy, they have incentives to support boards that the marginal trader dislikes. This consideration amplifies their incentives to support activist boards. Essentially, buying shareholders support boards that are more activist than they are, since they internalize the negative effect that such boards will have on the value of the marginal trader, and thereby, on the share price.

In general, the set of boards that obtain the support of at least τ of the initial shareholders is limited.[24] In particular, Proposition 8 shows that the optimal board, as characterized by Proposition 7, is not always within this set. This is true especially if τ is large. In this case, the marginal voter is more conservative than the average post-trade shareholder in the conservative equilibrium (i.e., $-q_c < \beta_c$), and therefore, there are welfare gains from delegating the decision rights to a less conservative board, and in particular, to the optimal conservative board. In fact, notice that $1 - (1 - \tau)(1 - \lambda) > \tau$ of the initial shareholders are less conservative than the marginal voter, and yet, they cannot agree to delegate their voting rights to even a marginally less conservative board when τ is large. The reason for this collective action failure stems from the externality mentioned above: some moderate shareholders who are less conservative than the marginal voter are not willing to delegate their decision rights to a less conservative board (and in particular to the optimal conservative board) because doing so will also benefit the marginal trader and thereby increase the price they have to pay to buy the shares in the delegation equilibrium. As a result, welfare-improving boards, and in particular the optimal board, cannot garner sufficient support from initial shareholders when τ is large.

Overall, our analysis demonstrates that when voting occurs prior to trading, short-term trading considerations impose an externality and may push shareholders to make suboptimal delegation decisions in order to gain from trading.

7   Conclusion

In this paper we study the relationship between trading and voting in a model in which shareholders have identical information but heterogeneous preferences. They trade with each other before those who end up owning the shares vote on a proposal. One of our main conclusions is that the complementarity between trading and voting gives rise to multiple equilibria. Multiple equilibria arise with self-fulfilling expectations, in our case about the likelihood that the

---

[24]The proof of Proposition 8 in fact shows a more general result: Suppose shareholders expect the activist (conservative) equilibrium in the voting game. For any board with an activist (conservative) bias $b_m > -H^{-1}(\phi)$ $(b_m < -H^{-1}(\phi))$, there exists $\bar{\tau} \in (0, 1)$ such that if $\tau \in (\bar{\tau}, 1)$, then at least $1 - \tau$ initial shareholders strictly prefer retaining their voting rights over delegation to a board with bias b_m.

proposal is accepted: If shareholders expect a high likelihood that the proposal is accepted, then the activist equilibrium obtains, and vice versa for a low likelihood. This leaves us with the question of how shareholders coordinate on a particular equilibrium. One way of addressing this issue is to root expectation formation in the economic environment.[25] In our context there are multiple potential sources in the economic environment that may influence expectation formation. For example, some shareholders may be more visible, have better access to the media, or have other characteristics not included in our model that put them into a position to influence the expectations of other shareholders. Proxy advisory firms may perform a similar function and may have an influence on voting outcomes by coordinating shareholders' expectations. We hope that the future empirical literature will study how shareholders form expectations about governance outcomes, how these expectations affect trading before shareholder votes, and how these changes in the shareholder base affect voting outcomes.

The second important conclusion is that shareholder voting may not lead to optimal outcomes. First, there is no guarantee that shareholders coordinate on the welfare-maximizing equilibrium if there are multiple equilibria. Second, we show that delegation to a board of directors can improve shareholder welfare even if shareholders can coordinate on the welfare-maximizing voting equilibrium. Third, the welfare of current shareholders is not maximized with a board that best represents their preferences. Rather, it is maximized by a board that represents the interests of those shareholders who own the firm after trading, and thus the optimal board needs to be biased. Hence, observing that the board pursues interests different from those of the average shareholder is not sufficient for making a case for "shareholder democracy:" Such a divergence can indeed be optimal. The parallelism to political democracy breaks down in one important respect: Shareholders can trade, and trading aligns the shareholder base with the expected outcomes.[26]

---

[25]This is ultimately the reasoning behind the notion of a focal point (Schelling (1960)), which rests on the argument that economic agents rely on additional reasoning to coordinate on a particular equilibrium. See Sugden and Zamarron (2006) and Myerson (2009) for positive evaluations of this "pragmatic" approach to equilibrium selection, and Morris and Shin (2003) for a more critical stance on leaving expectation formation outside the model.

[26]Easterbrook and Fischel (1983) already pointed out this important difference when they argued that the ability to sell shares serves the same purpose as voting in a polity, which is designed to "elicit the views of the governed and to limit powerful states." (p. 396). The issue is still debated vigorously in the law literature, see

The model in this paper relies on heterogeneous preferences. However, the model could be easily modified to accommodate homogeneous preferences if we assume that shareholders have differences of opinions. In such a model, all shareholders would have the same bias, but each shareholder would have a different interpretation of the public signal about the proposal that all shareholders observe in our model.[27] The characterization of the equilibrium would remain similar, but the welfare analysis would require some adjustments, since models with differences of opinions lack objectively correct probability distributions. Exploring such an extension is left for future research.

Bebchuk (2005) and Bainbridge (2006).

[27]Some papers have explored differences of opinions in relation to corporate governance theoretically (Boot, Gopalan, and Thakor (2006), Kakhbod et al. (2019)) and empirically (Li, Maug, and Schwartz-Ziv (2019)).

8 Appendix - Proofs

This appendix presents the proofs of all results in the paper. Throughout the appendix, the cutoff q^* can potentially fall out of the support of the distribution of q, $[-\Delta, \Delta]$. In this case, if $q^* \geq \Delta$, we set $H(q^*) = 0$, $H(q^*)\mathbb{E}[\theta|q > q^*] = 0$, and $f(q^*) = 0$. Similarly, if $q^* \leq -\Delta$, we set $H(q^*) = 1$, $H(q^*)\mathbb{E}[\theta|q > q^*] = \mathbb{E}[\theta] = 0$, and $f(q^*) = 0$.

Proof of Lemma 1. Given the realization of q, a shareholder indexed by b votes his shares for the proposal if and only if $q > -b$. Denote the fraction of post-trade shares voted to approve the proposal by $\Lambda(q)$. Note that $\Lambda(q)$ is weakly increasing (everyone who votes "for" given a smaller q will also vote "for" given a larger q, and there might be a non-negative mass of new shareholders who start voting "for"). If, for the lowest possible $q = -\Delta$, we have $\Lambda(-\Delta) > \tau$, then q^* in the statement of the lemma is equal to -1 (because the proposal is always approved). Similarly, if for the highest possible $q = \Delta$, we have $\Lambda(\Delta) \leq \tau$, then q^* in the statement of the lemma is equal to Δ (because the proposal is never approved). Finally, if $\Lambda(-\Delta) \leq \tau < \Lambda(\Delta)$, there exists $q^* \in [-\Delta, \Delta)$ such that the fraction of votes voted in favor of the proposal is greater than τ if and only if $q > q^*$. Hence, the proposal is approved if and only if $q > q^*$. ∎

Proof of Proposition 2. We consider three cases. First, suppose $H(q^*) > \phi$. In this case, $v(b, q^*)$ increases in b, and a shareholder with a bias b buys x shares if

$$v(b, q^*) > p \Leftrightarrow b > b_a \equiv \frac{p - v_0 - H(q^*)\mathbb{E}[\theta|q > q^*]}{H(q^*) - \phi},$$

and sells e shares if $v(b, q^*) < p$. Therefore, the total demand for shares is $D(p) = x \Pr[b > b_a]$ and the total supply of shares is $S(p) = e \Pr[b < b_a]$. The market clears if and only if $D(p) = S(p) \Leftrightarrow$

$$\Pr[b < b_a] = \frac{x}{x + e} = \lambda \Leftrightarrow b_a = G^{-1}(\lambda).$$

Since $\lambda \in (0, 1)$, we have $b_a \in (-\bar{b}, \bar{b})$. The price that clears the market is the valuation of the marginal trader b_a, and therefore, $p = v(b_a, q^*)$, as required.

Second, suppose $H(q^*) < \phi$. In this case, $v(b, q^*)$ decreases in b, and a shareholder with

bias b buys x shares if

$$v\left(b, q^*\right) > p \Leftrightarrow b < b_c \equiv \frac{p - v_0 - H\left(q^*\right) \mathbb{E}\left[\theta | q > q^*\right]}{H\left(q^*\right) - \phi},$$

and sells e shares if $v\left(b, q^*\right) < p$. Therefore, the total demand for shares is $D\left(p\right) = x \Pr\left[b < b_c\right]$ and the total supply of shares is $S\left(p\right) = e \Pr\left[b > b_c\right]$. The market clears if and only if $D\left(p\right) = S\left(p\right) \Leftrightarrow$

$$\Pr\left[b < b_c\right] = \frac{e}{x + e} = 1 - \lambda \Leftrightarrow b_c = G^{-1}\left(1 - \lambda\right).$$

Since $\lambda \in \left(0, 1\right)$, we have $b_c \in \left(-\bar{b}, \bar{b}\right)$. The price that clears the market is the valuation of the marginal trader b_c, and therefore, $p = v\left(b_c, q^*\right)$, as required.

Finally, suppose $H\left(q^*\right) = \phi$. In this case, the expected value of each shareholder is

$$v\left(b, q^*\right) = v_0 + H\left(q^*\right) \mathbb{E}\left[\theta | q > q^*\right] = v_0 + \phi \mathbb{E}\left[\theta | q > q^*\right].$$

The market can clear only if $p = v_0 + \phi \mathbb{E}\left[\theta | q > q^*\right]$, since otherwise, either all shareholders would want to buy shares or all shareholders would want to sell their shares. Notice that shareholder value does not depend on b, and that market clearing implies that all shareholders are indifferent between buying and selling shares. Based on the tie-breaking rule we adopt, shareholders will not trade. ∎

Proof of Proposition 3. According to Lemma 1, any equilibrium is characterized by some cutoff q^* at the voting stage. We consider three cases.

First, suppose that $H\left(q^*\right) > \phi$ (activist equilibrium). The arguments in the proof of Proposition 2 can again be repeated word for word. In particular, the marginal trader is b_a as given by (7), and after the trading stage, the shareholder base consists entirely of shareholders with $b > b_a$. Consider a realization of q. If $q > -b_a$, the proposal is accepted ($b > b_a > -q$ for all shareholders of the firm). If $q < -b_a$, then shareholders who vote in favor are those with $b \in \left(-q, \bar{b}\right]$ out of $b \in \left(b_a, \bar{b}\right]$, which gives a fraction of $\Pr\left[-q < b | b_a < b\right]$ affirmative votes. Hence, the proposal is accepted if and only if either (1) $q > -b_a$ or (2) $q < -b_a$ and $\Pr\left[-q < b | b_a < b\right] > \tau$, where the condition in (1) is equivalent to $q > -G^{-1}\left(\lambda\right)$, and the

conditions in (2) are together equivalent to

$$\Pr\left[-q < b | b_a < b, q < -b_a\right] \quad > \quad \tau \Leftrightarrow 1 - G\left(-q\right) > \tau\left(1 - G\left(b_a\right)\right) = \tau\left(1 - \lambda\right)$$

$$\Leftrightarrow \quad q > -G^{-1}\left(1 - \tau\left(1 - \lambda\right)\right).$$

Hence, the proposal is accepted if and only if $q > q_a = \min\{-G^{-1}\left(\lambda\right), -G^{-1}\left(1 - \tau\left(1 - \lambda\right)\right)\}$, and since $\lambda < 1 - \tau\left(1 - \lambda\right)$, the cutoff in this "activist" equilibrium is q_a as given by (9). Similarly to the proof of Proposition 2, the share price is $p_a = v\left(b_a, q_a\right)$.

Second, suppose that $H\left(q^*\right) < \phi$ (conservative equilibrium). The arguments in the proof of Proposition 2 can again be repeated here. In particular, the marginal trader is b_c as given by (8), and after the trading stage, the shareholder base consists entirely of shareholders with $b < b_c$. Consider a realization of q. Recall that shareholder b votes for the proposal if and only if $q > -b$. Hence, if $q < -b_c$, all shareholders of the firm vote against $(b < b_c < -q)$, so the proposal is rejected. If $q > -b_c$, then shareholders who vote in favor are those with $b \in (-q, b_c)$ out of $b \in [-\bar{b}, b_c)$, which gives a fraction of $\Pr\left[-q < b < b_c | b < b_c\right]$ affirmative votes. Hence, the proposal is accepted if and only if $-q < b_c$ and $\tau < \Pr\left[-q < b < b_c | b < b_c\right]$, which are together equivalent to

$$\tau \quad < \quad \frac{\Pr\left[b < b_c\right] - \Pr\left[b < -q\right]}{\Pr\left[b < b_c\right]} \Leftrightarrow \Pr\left[b < -q\right] < \left(1 - \tau\right)\Pr\left[b < b_c\right]$$

$$\Leftrightarrow \quad G\left(-q\right) < \left(1 - \tau\right)\left(1 - \lambda\right) \Leftrightarrow q > -G^{-1}\left(\left(1 - \tau\right)\left(1 - \lambda\right)\right).$$

Hence, the cutoff in this "conservative" equilibrium is q_c, given by (10). Similarly to the proof of Proposition 2, the share price is $p_c = v\left(b_c, q_c\right)$.

Third, suppose $H\left(q^*\right) = \phi$. In this case, the value of each shareholder is

$$v\left(b, q^*\right) = v_0 + H\left(q^*\right)\mathbb{E}\left[\theta | q > q^*\right] = v_0 + \phi\mathbb{E}\left[\theta | q > q^*\right].$$

Therefore, the market can clear only if $p = v_0 + \phi\mathbb{E}\left[\theta | q > q^*\right]$. Notice that shareholder value does not depend on b, and that market clearing implies that all shareholders are indifferent between buying and selling shares. Based on the tie-breaking rule we adopt, shareholders will not trade. Therefore, the post-trade shareholder base is identical to the pre-trade shareholder base. Next, note that $H\left(q^*\right) = \phi$ implies that the proposal is accepted if and only if $q > F^{-1}\left(1 - \phi\right)$. Since a shareholder votes for the proposal if and only if $q > -b$, it must be that

the fraction of initial shareholders with $F^{-1}(1-\phi) > -b$ is exactly τ, which is equivalent to $1 - G(-F^{-1}(1-\phi)) = \tau$, or $G^{-1}(1-\tau) = -F^{-1}(1-\phi)$. This is a knife-edge case that we ignore, since it does not hold generically.

Finally, notice that $q_a < q_c$, and therefore, either $H(q_c) < \phi$, or $H(q_a) > \phi$, or both. Therefore, an equilibrium always exists (but may be non-unique if $H(q_c) < \phi < H(q_a)$). This completes the proof.

As a side note, notice also that many other tie-breaking rules, those in which all shareholders follow the same strategy upon indifference (e.g., buy $r \in [-e, x]$ shares), would also eliminate this type of equilibrium. Indeed, if all shareholders buy or sell a certain (the same across shareholders) amount of shares upon indifference, the market is unlikely to clear. For the market to clear, shareholders with different biases would need to behave differently when they are indifferent between buying and selling shares, that is, the tie-breaking rule has to differ across shareholders in a particular way. Since such a tie-breaking rule is somewhat arbitrary, we ruled it out as an unlikely outcome. ∎

Proof of Proposition 4. Note that condition (11) can be written as

$$(1-\lambda)(1-\tau) < G\left(-F^{-1}(1-\phi)\right) < 1 - \tau(1-\lambda). \tag{19}$$

To see the point about λ, note that (19) is equivalent to

$$\lambda > \max\left\{1 - \frac{G\left(-F^{-1}(1-\phi)\right)}{1-\tau}, 1 - \frac{1 - G\left(-F^{-1}(1-\phi)\right)}{\tau}\right\}.$$

To see the point about τ, note that (19) is equivalent to

$$1 - \frac{G\left(-F^{-1}(1-\phi)\right)}{1-\lambda} < \tau < \frac{1 - G\left(-F^{-1}(1-\phi)\right)}{1-\lambda}.$$

To see the point about ϕ, note that (19) is equivalent to

$$1 - F\left(-G^{-1}((1-\lambda)(1-\tau))\right) < \phi < 1 - F\left(-G^{-1}(1 - \tau(1-\lambda))\right).$$

Finally, notice that as $\bar{b} \to 0$, the bias of the post-trade shareholder base becomes homogeneous at zero, and in particular, the marginal voter must converge to zero as well. This implies

$\lim_{\bar{b} \to 0} q^* = 0$ in any equilibrium, and thus, the voting equilibrium must be unique: it is an activist equilibrium if and only if $H(0) < \phi$. Therefore, condition (11) can be satisfied only if $\bar{b}$ is sufficiently large, as required. ∎

Proof of Lemma 2. Recall that in the conservative equilibrium, market clearing implies $\Pr[b > b_c] e = \Pr[b < b_c] x$, where $\Pr[b < b_c] = 1 - \lambda = \frac{e}{x+e}$. Therefore,

$$
\begin{aligned}
W_c &= \Pr[b > b_c] e p_c + \Pr[b < b_c] \mathbb{E}[(e+x) v(b, q_c) - x p_c | b < b_c] \\
&= \Pr[b < b_c] x p_c + \Pr[b < b_c] \mathbb{E}[(e+x) v(b, q_c) - x p_c | b < b_c] \\
&= \Pr[b < b_c] \mathbb{E}[(e+x) v(b, q_c) | b < b_c] = (1 - \lambda)(e+x) \mathbb{E}[v(b, q_c) | b < b_c] \\
&= e \mathbb{E}[v(b, q_c) | b < b_c] = e v(\mathbb{E}[b | b < b_c], q_c) = e v(\beta_c, q_c),
\end{aligned}
$$

where the second to last equality follows from the linearity of $v(b, q_c)$ in b.

Similarly, in the activist equilibrium, market clearing implies $\Pr[b < b_a] e = \Pr[b > b_a] x$, where $\Pr[b > b_a] = 1 - \lambda = \frac{e}{x+\varepsilon}$. Therefore,

$$
\begin{aligned}
W_a &= \Pr[b < b_a] e p_a + \Pr[b > b_a] \mathbb{E}[(e+x) v(b, q_a) - x p_a | b > b_a] \\
&= \Pr[b > b_a] x p_a + \Pr[b > b_a] \mathbb{E}[(e+x) v(b, q_a) - x p_a | b > b_a] \\
&= \Pr[b > b_a] \mathbb{E}[(e+x) v(b, q_a) | b > b_a] = (1 - \lambda)(e+x) \mathbb{E}[v(b, q_a) | b > b_a] \\
&= e \mathbb{E}[v(b, q_a) | b > b_a] = e v(\mathbb{E}[b | b > b_a], q_a) = e v(\beta_a, q_a).
\end{aligned}
$$

∎

Proof of Proposition 5. Consider the conservative equilibrium. Recall that in this equilibrium $W_c = e \cdot v(\beta_c, q_c)$ and $p_c = v(b_c, q_c)$. Then, a change in parameters that affects the marginal voter (q_c) without changing the marginal trader only affects W_c and p_c through its effect on q_c. Also recall that based on (16), $v(\beta_c, q^*)$ is a hump-shaped function in q^* with a maximum at $q^* = -\beta_c$, and $v(b_c, q^*)$ is a hump-shaped function in q^* with a maximum at $q^* = -b_c$. Since $-b_c < q_c - \beta_c$ by assumption of the proposition, any small enough change in parameters that leaves this order unchanged $(-b_c < q_c - \beta_c)$ either increases the distance of q_c to $-\beta_c$ but decreases the distance to $-b_c$, or vice versa. Hence, this change of parameters necessarily moves prices and welfare in opposite directions.

46

Consider the activist equilibrium. Recall that in this equilibrium $W_a = e \cdot v\left(\beta_a, q_a\right)$ and $p_a = v\left(b_a, q_a\right)$. Then, a change in parameters that affects the marginal voter $\left(q_a\right)$ without changing the marginal trader only affects W_a and p_a through its effect on q_a. Also recall that based on (16), $v\left(\beta_a, q^*\right)$ is a hump-shaped function in q^* with a maximum at $q^* = -\beta_a$, and $v\left(b_a, q^*\right)$ is a hump-shaped function in q^* with a maximum at $q^* = -b_a$. Since $-b_a < q_a - \beta_a$ by assumption of the proposition, any small enough change in parameters that leaves this order unchanged $\left(-b_a < q_a - \beta_a\right)$ either increases the distance to $-\beta_a$ but decreases the distance to $-b_a$, or vice versa. Hence, this change of parameters necessarily moves prices and welfare in opposite directions. ∎

Proof of Lemma 4. Based on Proposition 2, the share price is

$$p_{NoVote}\left(q^*\right) = v_0 + H\left(q^*\right)\mathbb{E}\left[q|q > q^*\right] + \begin{cases} b_c\left(H\left(q^*\right) - \phi\right) & \text{if } H\left(q^*\right) < \phi \\ b_a\left(H\left(q^*\right) - \phi\right) & \text{if } H\left(q^*\right) > \phi, \end{cases}$$

and the expected shareholder welfare is

$$W_{NoVote}\left(q^*\right) = e \cdot \left[v_0 + H\left(q^*\right)\mathbb{E}\left[q|q > q^*\right] + \begin{cases} \beta_c\left(H\left(q^*\right) - \phi\right) & \text{if } H\left(q^*\right) < \phi \\ \beta_a\left(H\left(q^*\right) - \phi\right) & \text{if } H\left(q^*\right) > \phi. \end{cases}\right]$$

Recall that $b_c = G^{-1}\left(1 - \lambda\right)$, $\beta_c = \mathbb{E}\left[b|b < b_c\right]$, $b_a = G^{-1}\left(\lambda\right)$, and $\beta_a = \mathbb{E}\left[b|b > b_a\right]$. Thus, $p_{NoVote}\left(q^*\right)$ and $W_{NoVote}\left(q^*\right)$ depend on λ only through their effect on b_c and b_a. Since, by Corollary 1, b_c and β_c are decreasing in λ, and b_a and β_a are increasing in λ, both $p_{NoVote}\left(q^*\right)$ and $W_{NoVote}\left(q^*\right)$ increase in λ. ∎

Proof of Proposition 6. First, consider the conservative equilibrium, which exists if and only if $H\left(q_c\right) < \phi$. Recall $p_c = v\left(b_c, q_c\right)$ and $W_c = e \cdot v\left(\beta_c, q_c\right)$, where $b_c = G^{-1}\left(1 - \lambda\right)$, $\beta_c = \mathbb{E}\left[b|b < b_c\right] = \frac{1}{G\left(b_c\right)}\int_{-b}^{b_c} bdG\left(b\right)$, and $q_c = -G^{-1}\left(\left(1 - \lambda\right)\left(1 - \tau\right)\right)$. Using (6),

$$\frac{\partial p_c}{\partial \lambda} = \frac{\partial b_c}{\partial \lambda}\left(H\left(q_c\right) - \phi\right) - \left(b_c + q_c\right)\frac{\partial q_c}{\partial \lambda}f\left(q_c\right) \tag{20}$$

and

$$\frac{1}{e}\frac{\partial W_c}{\partial \lambda} = \frac{\partial \beta_c}{\partial \lambda}\left(H\left(q_c\right) - \phi\right) - \left(\beta_c + q_c\right)\frac{\partial q_c}{\partial \lambda}f\left(q_c\right). \tag{21}$$

47

More precisely, (20)-(21) hold when $q_c \in (-\Delta, \Delta)$, and when q_c is outside these bounds, the second term in both of these expressions is equal to zero (as noted above, we set $f(q^*) = 0$ for $q^* \notin (-\Delta, \Delta)$).

Using (10) and (8), we get $\frac{\partial q_c}{\partial \lambda} = \frac{1-\tau}{g(-q_c)} > 0$, $\frac{\partial b_c}{\partial \lambda} = -\frac{1}{g(b_c)} < 0$, and

$$\frac{\partial \beta_c}{\partial \lambda} = \frac{\frac{\partial b_c}{\partial \lambda} b_c g(b_c) G(b_c) - \left[\int_{-\bar{b}}^{b_c} b g(b)\, db\right] g(b_c) \frac{\partial b_c}{\partial \lambda}}{[G(b_c)]^2} = \frac{\partial b_c}{\partial \lambda} \frac{g(b_c)}{G(b_c)} (b_c - \beta_c) = -\frac{b_c - \beta_c}{G(b_c)} < 0.$$

Plugging into (20) and (21), we get

$$\frac{\partial p_c}{\partial \lambda} = -\frac{H(q_c) - \phi}{g(b_c)} - (1-\tau)(b_c + q_c)\frac{f(q_c)}{g(-q_c)}$$

$$\frac{1}{e}\frac{\partial W_c}{\partial \lambda} = -\frac{H(q_c) - \phi}{G(b_c)}(b_c - \beta_c) - (1-\tau)(\beta_c + q_c)\frac{f(q_c)}{g(-q_c)},$$

where again, the second term is zero if $q_c \notin (-\Delta, \Delta)$. Notice that as $\lambda \to 1$, then b_c, β_c, and $-q_c$ all converge to $-\bar{b}$, and $H(q_c) - \phi \to H(\bar{b}) - \phi$. Suppose the conservative equilibrium exists in the limit (which is the case if $H(\bar{b}) < \phi$). Since g is positive on $[-\bar{b}, \bar{b}]$,

$$\lim_{\lambda \to 1} \frac{\partial p_c}{\partial \lambda} = -\frac{H(\bar{b}) - \phi}{g(-\bar{b})} > 0.$$

In addition, $\lim_{\lambda \to 1}\frac{1}{e}\frac{\partial W_c}{\partial \lambda} = -\left(H(\bar{b}) - \phi\right)\lim_{\lambda \to 1}\frac{b_c - \beta_c}{G(b_c)}$. Using l'Hopital's rule,

$$\lim_{\lambda \to 1}\frac{b_c - \beta_c}{G(b_c)} = \lim_{\lambda \to 1}\frac{\frac{\partial b_c}{\partial \lambda} - \frac{\partial \beta_c}{\partial \lambda}}{g(b_c)\frac{\partial b_c}{\partial \lambda}} = \frac{1}{g(-\bar{b})} - \lim_{\lambda \to 1}\frac{b_c - \beta_c}{G(b_c)},$$

which implies $\lim_{\lambda \to 1}\frac{b_c - \beta_c}{G(b_c)} = \frac{1}{2}\frac{1}{g(-\bar{b})} > 0$, and hence $\lim_{\lambda \to 1}\frac{\partial W_c}{\partial \lambda} > 0$.

Also notice that as $\lambda \to 0$, then $b_c \to \bar{b}$, $\beta_c \to \mathbb{E}[b]$, and $q_c \to q_{NoTrade} = -G^{-1}(1-\tau) > -\bar{b}$. Suppose the conservative equilibrium exists in this limit (which is the case if $H(q_{NoTrade}) < \phi$). Then, using (20),

$$\lim_{\lambda \to 0}\frac{\partial p_c}{\partial \lambda} = -\frac{H(q_{NoTrade}) - \phi}{g(\bar{b})} - (1-\tau)(\bar{b} + q_{NoTrade})\frac{f(q_{NoTrade})}{g(-q_{NoTrade})},$$

where the second term is strictly negative because (1) by assumption, $q_{NoTrade} \in (-\Delta, \Delta)$, and (2) $\bar{b} + q_{NoTrade} > 0$, as shown above. Hence, $\lim_{\lambda \to 0}\frac{\partial p_c}{\partial \lambda} < 0$ if $|H(q_{NoTrade}) - \phi|$ is sufficiently

48

small.

Also notice that

$$\lim_{\lambda \to 0} \frac{1}{e} \frac{\partial W_c}{\partial \lambda} = -\frac{H\left(q_{NoTrade}\right) - \phi}{G\left(\bar{b}\right)} \left(\bar{b} - \mathbb{E}\left[b\right]\right) - (1 - \tau)\left(\mathbb{E}\left[b\right] + q_{NoTrade}\right) \frac{f\left(q_{NoTrade}\right)}{g\left(-q_{NoTrade}\right)}.$$

Thus, if $\lim_{\lambda \to 0}\left(\beta_c + q_c\right) = \mathbb{E}\left[b\right] + q_{NoTrade} > 0$ (i.e., the marginal voter is more extreme than the average post-trade shareholder) and $|H\left(q_{NoTrade}\right) - \phi|$ is small enough, then $\lim_{\lambda \to 0} \frac{\partial W_c}{\partial \lambda} < 0$.

Second, consider the activist equilibrium, which exists if and only if $H\left(q_a\right) - \phi > 0$. Similarly to the above, recall $p_a = v\left(b_a, q_a\right)$ and $W_a = e \cdot v\left(\beta_a, q_a\right)$, where $b_a = G^{-1}\left(\lambda\right)$, $\beta_a = \mathbb{E}\left[b | b > b_a\right] = \frac{1}{G(1 - b_a)} \int_{b_a}^{\bar{b}} bdG\left(b\right)$, and $q_a = -G^{-1}\left(1 - \tau\left(1 - \lambda\right)\right)$. Using (6),

$$\frac{\partial p_a}{\partial \lambda} = \frac{\partial b_a}{\partial \lambda}\left(H\left(q_a\right) - \phi\right) - \left(b_a + q_a\right) \frac{\partial q_a}{\partial \lambda} f\left(q_a\right) \tag{22}$$

and

$$\frac{1}{e} \frac{\partial W_a}{\partial \lambda} = \frac{\partial \beta_a}{\partial \lambda}\left(H\left(q_a\right) - \phi\right) - \left(\beta_a + q_a\right) \frac{\partial q_a}{\partial \lambda} f\left(q_a\right). \tag{23}$$

More precisely, (22)-(23) hold when $q_a \in \left(-\Delta, \Delta\right)$, and when q_a is outside these bounds, the second term in both of these expressions is equal to zero (as noted above, we set $f\left(q^*\right) = 0$ for $q^* \notin \left(-\Delta, \Delta\right)$).

Using (9) and (7), we get $\frac{\partial q_a}{\partial \lambda} = -\frac{\tau}{g\left(-q_a\right)} < 0$, $\frac{\partial b_a}{\partial \lambda} = \frac{1}{g\left(b_a\right)} > 0$, and

$$\begin{aligned} \frac{\partial \beta_a}{\partial \lambda} &= \frac{-\frac{\partial b_a}{\partial \lambda} b_a g\left(b_a\right)\left[1 - G\left(b_a\right)\right] + \left[\int_{b_a}^{\bar{b}} bg\left(b\right) db\right] g\left(b_a\right) \frac{\partial b_a}{\partial \lambda}}{\left[1 - G\left(b_a\right)\right]^2} \\ &= \frac{\partial b_a}{\partial \lambda} \frac{g\left(b_a\right)}{1 - G\left(b_a\right)}\left(\beta_a - b_a\right) = \frac{\beta_a - b_a}{1 - G\left(b_a\right)} > 0. \end{aligned}$$

Plugging into (22) and (23), we get

$$\begin{aligned} \frac{\partial p_a}{\partial \lambda} &= \frac{H\left(q_a\right) - \phi}{g\left(b_a\right)} + \tau\left(b_a + q_a\right) \frac{f\left(q_a\right)}{g\left(-q_a\right)} \\ \frac{1}{e} \frac{\partial W_a}{\partial \lambda} &= \frac{H\left(q_a\right) - \phi}{1 - G\left(b_a\right)}\left(\beta_a - b_a\right) + \tau\left(\beta_a + q_a\right) \frac{f\left(q_a\right)}{g\left(-q_a\right)}, \end{aligned}$$

where again, the second term is zero if $q_a \notin \left(-\Delta, \Delta\right)$. Notice that as $\lambda \to 1$, then b_a, β_a, and $-q_a$ all converge to $\bar{b}$, and $H\left(q_a\right) - \to H\left(-\bar{b}\right) - \phi$. Suppose the activist equilibrium exists in

49

the limit (which is the case if $H\left(-\bar{b}\right) > \phi$). Since g is positive on $\left[-\bar{b}, \bar{b}\right]$,

$$\lim_{\lambda \to 1} \frac{\partial p_a}{\partial \lambda} = \frac{H\left(-\bar{b}\right) - \phi}{g(\bar{b})} > 0.$$

In addition, $\lim_{\lambda \to 1} \frac{1}{e} \frac{\partial W_a}{\partial \lambda} = \left(H\left(-\bar{b}\right) - \phi\right) \lim_{\lambda \to 1} \frac{\beta_a - b_a}{1 - G(b_a)}$. Using l'Hopital's rule,

$$\lim_{\lambda \to 1} \frac{\beta_a - b_a}{1 - G\left(b_a\right)} = \lim_{\lambda \to 1} \frac{\frac{\partial \beta_a}{\partial \lambda} - \frac{\partial b_a}{\partial \lambda}}{-g\left(b_a\right) \frac{\partial b_a}{\partial \lambda}} = \frac{1}{g\left(\bar{b}\right)} - \lim_{\lambda \to 1} \frac{\beta_a - b_a}{1 - G\left(b_a\right)}$$

which implies $\lim_{\lambda \to 1} \frac{\beta_a - b_a}{1 - G(b_a)} = \frac{1}{2} \frac{1}{g(\bar{b})} > 0$. Therefore, $\lim_{\lambda \to 1} \frac{\partial W_a}{\partial \lambda} > 0$.

Also notice that as $\lambda \to 0$, then $b_a \to -\bar{b}$, $\beta_a \to \mathbb{E}\left[b\right]$, and $q_a \to q_{NoTrade} = -G^{-1}\left(1 - \tau\right) < \bar{b}$. Suppose the activist equilibrium exists in this limit (which is the case if $H\left(q_{NoTrade}\right) > \phi$). Then

$$\lim_{\lambda \to 0} \frac{\partial p_a}{\partial \lambda} = \frac{H\left(q_{NoTrade}\right) - \phi}{g\left(-\bar{b}\right)} + \tau\left(-\bar{b} + q_{NoTrade}\right) \frac{f\left(q_{NoTrade}\right)}{g\left(-q_{NoTrade}\right)},$$

where the second term is strictly negative because (1) by assumption, $q_{NoTrade} \in \left(-\Delta, \Delta\right)$, and (2) $-\bar{b} + q_{NoTrade} < 0$, as shown above. Hence, $\lim_{\lambda \to 0} \frac{\partial p_a}{\partial \lambda} < 0$ if $\left|H\left(q_{NoTrade}\right) - \phi\right|$ is sufficiently small. Also notice that

$$\lim_{\lambda \to 0} \frac{1}{e} \frac{\partial W_a}{\partial \lambda} = \frac{H\left(q_{NoTrade}\right) - \phi}{1 - G\left(b_a\right)} \left(\mathbb{E}\left[b\right] + \bar{b}\right) + \tau\left(\mathbb{E}\left[b\right] + q_{NoTrade}\right) \frac{f\left(q_{NoTrade}\right)}{g\left(-q_{NoTrade}\right)}.$$

Thus, if $\lim_{\lambda \to 0}\left(\beta_a + q_a\right) = \mathbb{E}\left[b\right] + q_{NoTrade} < 0$ (i.e., the marginal voter is more extreme than the average post-trade shareholder) and $\left|H\left(q_{NoTrade}\right) - \phi\right|$ is small enough, then $\lim_{\lambda \to 0} \frac{\partial W_a}{\partial \lambda} < 0$.

Given the strictly positive (negative) limits of $\frac{\partial p}{\partial \lambda}$ and $\frac{\partial W}{\partial \lambda}$ as $\lambda \to 1$ ($\lambda \to 0$) for any equilibrium as long as it exists, it follows that under the conditions of the proposition, there exist $\underline{\lambda}$ and $\bar{\lambda}$, $0 < \underline{\lambda} < \bar{\lambda} < 1$, such that both the share price and welfare in any equilibrium that exists increase (decrease) in λ for $\lambda > \bar{\lambda}$ ($\lambda < \bar{\lambda}$), as required. ∎

Proof of Proposition 7. We start by noting that if $q^* = H^{-1}\left(\phi\right)$, then all shareholders are indifferent between buying and selling, and the tie-breaking rule we adopt implies that in equilibrium, no shareholder trades. While this tie-breaking rule implies that the trading strategies of shareholders in the delegation equilibrium are not continuous in q^* as $q^* \to H^{-1}\left(\phi\right)$, the expected welfare of shareholders in any equilibrium continuously converges to

welfare in the equilibrium with $q^* = H^{-1}(\phi)$. Indeed, shareholder welfare in the equilibrium in which $q^* = H^{-1}(\phi)$ and shareholders thus do not trade is

$$e \cdot \mathbb{E}\left[v\left(b, H^{-1}(\phi)\right)\right] = e \cdot v\left(\mathbb{E}[b], H^{-1}(\phi)\right) = e \cdot \left(v_0 + \phi\mathbb{E}\left[\theta|q > H^{-1}(\phi)\right]\right). \quad (24)$$

Using (15) and (6), it is easy to see that the limit of shareholder welfare in both the conservative equilibrium $(e \cdot \lim_{q^* \searrow H^{-1}(\phi)} v(\beta_c, q^*))$ and in the activist equilibrium $(e \cdot \lim_{q^* \nearrow H^{-1}(\phi)} v(\beta_a, q^*))$ is the same and equals (24), as required.

Proof of the expressions for b_m^* and W_m^* in (18). The choice of the optimal board is equivalent to choosing the cutoff q^* that maximizes expected shareholder welfare. Recall from Section 5 and (16) that $v(b, q^*)$ is a hump-shaped function in q^* with a maximum at $q^* = -b$. Thus, within the range of q^* that generates a conservative equilibrium or the equilibrium where shareholders are indifferent and do not trade $(H(q^*) \leq \phi \Leftrightarrow q^* \geq H^{-1}(\phi))$, (15) implies that the optimal cutoff q^* is the point closest to $-\beta_c$ in this range, i.e., $\max\{-\beta_c, H^{-1}(\phi)\}$. Similarly, within the range of q^* that generates an activist equilibrium or the equilibrium where shareholders are indifferent and do not trade $(H(q^*) \geq \phi \Leftrightarrow q^* \leq H^{-1}(\phi))$, the optimal cutoff q^* is the point closest to $-\beta_a$ in this range, i.e., $\min\{-\beta_a, H^{-1}(\phi)\}$. Since $\beta_c < \beta_a$, there are three cases to consider.

1. If $H^{-1}(\phi) \leq -\beta_a$, then any $q^* < H^{-1}(\phi)$ generates an activist equilibrium, and it is welfare inferior to the equilibrium with $q^* = H^{-1}(\phi)$. At the same time, setting $q^* = -\beta_c$ would generate a conservative equilibrium that is superior to an equilibrium with $q^* = H^{-1}(\phi)$ because $-\beta_c > -\beta_a \geq H^{-1}(\phi)$. Therefore, in this case $b_m^* = \beta_c$.

2. If $-\beta_c \leq H^{-1}(\phi)$, then any $q^* > H^{-1}(\phi)$ generates a conservative equilibrium, and it is welfare inferior to an equilibrium with $q^* = H^{-1}(\phi)$. At the same time, setting $q^* = -\beta_a$ would generate an activist equilibrium that is superior to an equilibrium with $q^* = H^{-1}(\phi)$ because $-\beta_a < -\beta_c \leq H^{-1}(\phi)$. Therefore, in this case $b_m^* = \beta_a$.

3. If $-\beta_a < H^{-1}(\phi) < -\beta_c$, then the optimal cutoff among those that generate a conservative equilibrium is $-\beta_c$, and the optimal cutoff among those that generate an activist equilibrium is $-\beta_a$, and both generate higher welfare than $q^* = H^{-1}(\phi)$. Then, $b_m^* = \beta_a$

51

if $v\left(\beta_a, -\beta_a\right) > v\left(\beta_c, -\beta_c\right)$, and $b_m^* = \beta_c$ otherwise. Notice that

$$v\left(\beta_a, -\beta_a\right) > v\left(\beta_c, -\beta_c\right) \Leftrightarrow H^{-1}\left(\phi\right) > H^{-1}\left(\Phi\right) \Leftrightarrow \phi < \Phi, \tag{25}$$

where

$$
\begin{aligned}
\Phi \ &\equiv \ H(-\beta_c) + \mathbb{E}\left[\beta_a + q \mid -\beta_a < q < -\beta_c\right]\frac{H(-\beta_a) - H(-\beta_c)}{\beta_a - \beta_c} \\
&= \ H(-\beta_a) + \mathbb{E}\left[\beta_c + q \mid -\beta_a < q < -\beta_c\right]\frac{H(-\beta_a) - H(-\beta_c)}{\beta_a - \beta_c}.
\end{aligned}
\tag{26}
$$

Thus, $b_m^* = \beta_a$ if $\phi < \Phi \Leftrightarrow H^{-1}\left(\phi\right) > H^{-1}\left(\Phi\right)$ and $b_m^* = \beta_c$ if $\phi > \Phi \Leftrightarrow H^{-1}\left(\phi\right) < H^{-1}\left(\Phi\right)$. Also notice that $H\left(-\beta_a\right) > \Phi > H\left(-\beta_c\right)$, which implies $-\beta_a < H^{-1}\left(\Phi\right) < -\beta_c$.

Taken together, the three cases above imply that $b_m^* = \beta_c$ if either $H^{-1}\left(\phi\right) \leq -\beta_a$ or $-\beta_a < H^{-1}\left(\phi\right)$ and $H^{-1}\left(\phi\right) < H^{-1}\left(\Phi\right)$. Since $-\beta_a < H^{-1}\left(\Phi\right)$, these two conditions together imply that $b_m^* = \beta_c$ if $H^{-1}\left(\phi\right) < H^{-1}\left(\Phi\right) \Leftrightarrow \phi > \Phi$. And, the three cases above imply that $b_m^* = \beta_a$ if either $-\beta_c \leq H^{-1}\left(\phi\right)$ or $H^{-1}\left(\phi\right) < -\beta_c$ and $H^{-1}\left(\Phi\right) < H^{-1}\left(\phi\right)$. Since $H^{-1}\left(\Phi\right) < -\beta_c$, these two conditions together imply that $b_m^* = \beta_a$ if $H^{-1}\left(\phi\right) > H^{-1}\left(\Phi\right) \Leftrightarrow \phi < \Phi$. If $\phi = \Phi$, both β_a and β_c give the highest possible shareholder welfare.

We conclude that $b_m^* = \beta_a$ if $\phi < \Phi \Leftrightarrow v\left(\beta_a, -\beta_a\right) > v\left(\beta_c, -\beta_c\right)$ and $b_m^* = \beta_c$ otherwise. This proves (18).

Proof of (i). It automatically follows from (18) and the fact that $\beta_a = \mathbb{E}\left[b \mid b > b_a\right] > \mathbb{E}\left[b\right]$ and $\beta_c = \mathbb{E}\left[b \mid b < b_c\right] < \mathbb{E}\left[b\right]$.

Proof of (ii). According to (18), $W_m^* = e \cdot v\left(B, -B\right)$, where B is either β_c or β_a. We first prove that $v\left(B, -B\right)$ increases in B if and only if $H\left(-B\right) > \phi$. Indeed, based on (6),

$$
\begin{aligned}
v\left(B, -B\right) \ &= \ v_0 + B\left(H\left(-B\right) - \phi\right) + H\left(-B\right)\mathbb{E}\left[\theta \mid q > -B\right] \\
&= \ v_0 - \phi B + \int_{-B}\left(q + B\right)dF\left(q\right)
\end{aligned}
\tag{27}
$$

if $-B \in \left(-\Delta, \Delta\right)$. If $-B > \Delta$, the last term in (27) is zero, and if $-B < -\Delta$, the last term is B. Therefore, $\frac{\partial v(B, -B)}{\partial B} = H\left(-B\right) - \phi$ for all $-B$, as required.

From (18), W_m^* depends on λ only through its effect on b_a and b_c. First, suppose $\phi > \Phi$. Then $b_m^* = \beta_c$, and the equilibrium under the optimal board is conservative in the sense that

52

$H\left(-\beta_c\right) < \phi$. Then, $W_m^* = e \cdot v\left(B, -B\right)|_{B=\beta_c}$ and $\frac{\partial v(B,-B)}{\partial B}|_{B=\beta_c} < 0$. Since β_c decreases in λ, it follows that W_m^* increases in λ. Second, suppose $\phi < \Phi$. Then $b_m^* = \beta_a$, and the equilibrium under the optimal board is activist in the sense that $H\left(-\beta_a\right) > \phi$. Then, $W_m^* = e \cdot v\left(B, -B\right)|_{B=\beta_a}$ and $\frac{\partial v(B,-B)}{\partial B}|_{B=\beta_a} > 0$. Since β_a increases in λ, it follows that W_m^* increases in λ. Thus, if $\phi \neq \Phi$, then W_m^* increases in λ. If $\phi = \Phi$, then (25) implies $W_m^* = e \cdot v\left(\beta_c, -\beta_c\right) = e \cdot v\left(\beta_a, -\beta_a\right)$, and since both terms increase in λ, so does W_m^*.

Proof of (iii). Notice that the delegation equilibrium can replicate any conservative (activist) voting equilibrium if we set $b_m = -q_c$ ($b_m = -q_a$). Therefore, delegation to the optimal board always weakly dominates the voting equilibrium and strictly dominates it except the knife-edge cases when the voting equilibrium is already efficient, i.e., $q_c = -b_m^*$ or $q_a = -b_m^*$. Moreover, except for these knife-edge cases, given the continuity of the expected welfare function around b_m^* and a strictly possible benefit of delegation at b_m^*, it follows that there is a neighborhood around b_m^* such that if the manager's bias is in that neighborhood, then the delegation equilibrium is strictly more efficient than the voting equilibrium. ∎

Proof of Proposition 8. If shareholder b expects the voting equilibrium to be conservative, then his expected payoff is $V_c\left(b, q_c\right)$, where

$$V_c\left(b, q^*\right) = \begin{cases} (e + x) v\left(b, q^*\right) - xv\left(b_c, q^*\right) & \text{if } b < b_c \\ ev\left(b_c, q^*\right) & \text{if } b \geq b_c. \end{cases} \tag{28}$$

Similarly, if shareholder b expects the delegation equilibrium to a board with bias $b_m = -q_m$ to be conservative, then his expected payoff is $V_c\left(b, q_m\right)$. Notice that the delegation equilibrium is conservative if and only if $H\left(q_m\right) < \phi \Leftrightarrow -q_m < -H^{-1}\left(\phi\right)$. If shareholder b expects the voting equilibrium to be activist, then his expected payoff is $V_a\left(b, q_a\right)$, where

$$V_a\left(b, q^*\right) = \begin{cases} (e + x) v\left(b, q^*\right) - xv\left(b_a, q^*\right) & \text{if } b > b_a \\ ev\left(b_a, q^*\right) & \text{if } b \leq b_a. \end{cases} \tag{29}$$

Similarly, if shareholder b expects the delegation equilibrium to a board with bias $b_m = -q_m$ to be activist, then his expected payoff is $V_a\left(b, q_m\right)$. Notice that the delegation equilibrium is activist if and only if $H\left(q_m\right) > \phi \Leftrightarrow -q_m > -H^{-1}\left(\phi\right)$.

To begin, suppose shareholders expect the voting equilibrium to be conserv-ative. Consider as an alternative a conservative board with bias $b_m = -q_m < -H^{-1}(\phi)$. Shareholder b prefers delegation to a conservative board with bias b_m over the conservative voting equilibrium if and only if $V_c(b, q_c) < V_c(b, q_m)$. We consider several cases:

1. If $b \geq b_c$, then

$$
\begin{aligned}
V_c(b, q_c) &< V_c(b, q_m) \Leftrightarrow v(b_c, q_c) < v(b_c, q_m) \Leftrightarrow \\
b_c(H(q_c) - H(q_m)) &< H(q_m)\,\mathbb{E}[\theta|q > q_m] - H(q_c)\,\mathbb{E}[\theta|q > q_c].
\end{aligned}
$$

   - If in addition $q_c < q_m$, then

$$
V_c(b, q_c) < V_c(b, q_m) \Leftrightarrow b_c < \mathbb{E}[-q| - q_m < -q < -q_c],
$$

   which never holds given that $-q_c < b_c$. Thus, shareholders $b \geq b_c$ never support delegation to a board who is more extreme than the marginal voter, i.e., $b_m < -q_c$.

   - If in addition $q_c > q_m$, then

$$
V_c(b, q_c) < V_c(b, q_m) \Leftrightarrow b_c > \mathbb{E}[-q| - q_c < -q < -q_m].
$$

   Thus, shareholders $b \geq b_c$ will support delegation to a board whenever $-q_m \in (-q_c, b_c]$, and might even do so if $-q_m > b_c$.

2. If $b < b_c$ then

$$
\begin{aligned}
V_c(b, q_c) < V_c(b, q_m) &\Leftrightarrow v(b, q_c) - \lambda v(b_c, q_c) < v(b, q_m) - \lambda v(b_c, q_m) \Leftrightarrow \\
v(b, q_c) - v(b, q_m) &< \lambda[v(b_c, q_c) - v(b_c, q_m)] \Leftrightarrow \\
b(H(q_c) - \phi) + H(q_c)\,\mathbb{E}[\theta|q > q_c] &- (b(H(q_m) - \phi) + H(q_m)\,\mathbb{E}[\theta|q > q_m]) \\
< \lambda[b_c(H(q_c) - \phi) + H(q_c)\,\mathbb{E}[\theta|q > q_c] &- (b_c(H(q_m) - \phi) + H(q_m)\,\mathbb{E}[\theta|q > q_m])] \Leftrightarrow \\
b(H(q_c) - H(q_m)) + H(q_c)\,\mathbb{E}[\theta|q > q_c] &- H(q_m)\,\mathbb{E}[\theta|q > q_m] \\
< \lambda[b_c(H(q_c) - H(q_m)) + H(q_c)\,\mathbb{E}[\theta|q > q_c] &- H(q_m)\,\mathbb{E}[\theta|q > q_m]].
\end{aligned}
$$

- If in addition $q_c < q_m$, then

$$V_c(b, q_c) < V_c(b, q_m) \Leftrightarrow b < \lambda b_c + (1 - \lambda) \mathbb{E}[-q] - q_m < -q < -q_c]$$

and notice that since $-q_c < b_c$, then

$$\lambda b_c + (1 - \lambda) \mathbb{E}[-q] - q_m < -q < -q_c] < b_c.$$

- If in addition $q_c > q_m$, then

$$V_c(b, q_c) < V_c(b, q_m) \Leftrightarrow b > \lambda b_c + (1 - \lambda) \mathbb{E}[-q] - q_c < -q < -q_m].$$

Overall, if $-q_m < -q_c$, then only shareholders with $b < \lambda b_c + (1 - \lambda) \mathbb{E}[-q] - q_m < -q < -q_c] < b_c$ support delegation to the board, and if $G(b_c) < \tau \Leftrightarrow 1 - \lambda < \tau$, then this type of board does not obtain τ-support. If $-q_m > -q_c$ and $b_c < \mathbb{E}[-q] - q_c < -q < -q_m]$, there is no support for delegation. However, if $-q_m > -q_c$ and $b_c > \mathbb{E}[-q] - q_c < -q < -q_m]$, then shareholders with $b > \lambda b_c + (1 - \lambda) \mathbb{E}[-q] - q_c < -q < -q_m]$ support delegation (notice that in this case $\lambda b_c + (1 - \lambda) \mathbb{E}[-q] - q_c < -q < -q_m] < b_c$). Notice that

$$1 - G(\lambda b_c + (1 - \lambda) \mathbb{E}[-q] - q_c < -q < -q_m]) < 1 - G(\lambda b_c - (1 - \lambda) q_c),$$

and recall $\lim_{\tau \to 1} q_c = \bar{b}$. Therefore, $\lim_{\tau \to 1} 1 - G(\lambda b_c - (1 - \lambda) q_c) = 1 - G(\lambda b_c - (1 - \lambda) \bar{b}) < 1$. Overall, we conclude that as $\tau \to 1$, no conservative board gains τ-support from shareholders if they expect the conservative voting equilibrium.

Next, suppose shareholders expect the voting equilibrium to be activist. Consider as an alternative an activist board with a bias $b_m = -q_m > -H^{-1}(\phi)$. Shareholder b prefers delegation to an activist board with bias b_m over the activist voting equilibrium if and only if $V_a(b, q_a) < V_a(b, q_m)$. We consider several cases:

1. If $b \leq b_a$, then

$$V_a(b, q_a) < V_a(b, q_m) \Leftrightarrow v(b_a, q_a) < v(b_a, q_m) \Leftrightarrow$$
$$b_a(H(q_a) - H(q_m)) < H(q_m) \mathbb{E}[\theta | q > q_m] - H(q_a) \mathbb{E}[\theta | q > q_a].$$

- If in addition $q_a > q_m$, then

$$V_a(b, q_a) < V_a(b, q_m) \Leftrightarrow b_a > \mathbb{E}\left[-q| -q_a < -q < -q_m\right],$$

which never holds given that $-q_a > b_a$. Thus, shareholders $b \leq b_a$ never support delegation to a board who is more extreme than the marginal voter, i.e., $b_m > -q_a$.

- If in addition $q_a < q_m$, then

$$V_a(b, q_a) < V_a(b, q_m) \Leftrightarrow b_a < \mathbb{E}\left[-q| -q_m < -q < -q_a\right].$$

Thus, shareholders $b \leq b_a$ will support delegation to a board whenever $-q_m \in [b_a, -q_a)$, and might even do so if $-q_m < b_a$.

2. If $b > b_a$, then

$$V_a(b, q_a) < V_a(b, q_m) \Leftrightarrow v(b, q_a) - \lambda v(b_a, q_a) < v(b, q_m) - \lambda v(b_a, q_m) \Leftrightarrow$$
$$v(b, q_a) - v(b, q_m) < \lambda\left[v(b_a, q_a) - v(b_a, q_m)\right] \Leftrightarrow$$
$$b(H(q_a) - \phi) + H(q_a)\mathbb{E}[\theta|q > q_a] - b(H(q_m) - \phi) - H(q_m)\mathbb{E}[\theta|q > q_m]$$
$$< \lambda\left[b_a(H(q_a) - \phi) + H(q_a)\mathbb{E}[\theta|q > q_a] - b_a(H(q_m) - \phi) - H(q_m)\mathbb{E}[\theta|q > q_m]\right] \Leftrightarrow$$
$$b(H(q_a) - H(q_m)) + H(q_a)\mathbb{E}[\theta|q > q_a] - H(q_m)\mathbb{E}[\theta|q > q_m]$$
$$< \lambda\left[b_a(H(q_a) - H(q_m)) + H(q_a)\mathbb{E}[\theta|q > q_a] - H(q_m)\mathbb{E}[\theta|q > q_m]\right].$$

- If in addition $q_a > q_m$, then

$$V_a(b, q_a) < V_a(b, q_m) \Leftrightarrow b > \lambda b_a + (1 - \lambda)\mathbb{E}\left[-q| -q_a < -q < -q_m\right]$$

and notice that since $-q_a > b_a$, then

$$b_a < \lambda b_a + (1 - \lambda)\mathbb{E}\left[-q| -q_a < -q < -q_m\right].$$

- If in addition $q_a < q_m$, then

$$V_a(b, q_a) < V_a(b, q_m) \Leftrightarrow b < \lambda b_a + (1 - \lambda)\mathbb{E}\left[-q| -q_m < -q < -q_a\right].$$

56

Overall, if $-q_m > -q_a$, then only shareholders with $b > \lambda b_a + (1 - \lambda)\,\mathbb{E}\left[-q| -q_a < -q < -q_m\right] > b_a$ support delegation to the board, and if $1 - G\left(b_a\right) < \tau \Leftrightarrow 1 - \lambda < \tau$, then this type of board does not obtain τ-support. If $-q_m < -q_a$ and $b_a > \mathbb{E}\left[-q| -q_m < -q < -q_a\right]$, then there is no support for delegation. However, if $-q_m < -q_a$ and $b_a < \mathbb{E}\left[-q| -q_m < -q < -q_a\right]$, then shareholders with $b < \lambda b_a + (1 - \lambda)\,\mathbb{E}\left[-q| -q_m < -q < -q_a\right]$ support delegation (notice that in this case $b_a < \lambda b_a + (1 - \lambda)\,\mathbb{E}\left[-q| -q_m < -q < -q_a\right]$). Notice that

$$G\left(\lambda b_a + (1 - \lambda)\,\mathbb{E}\left[-q| -q_m < -q < -q_a\right]\right) < G\left(\lambda b_a - (1 - \lambda)\,q_a\right),$$

and recall $\lim_{\tau \to 1} q_a = -b_a$. Therefore, $\lim_{\tau \to 1} G\left(\lambda b_a - (1 - \lambda)\,q_a\right) = G\left(b_a\right) < 1$. Overall, we conclude that as $\tau \to 1$, no activist board gains τ-support from shareholders if they expect the activist voting equilibrium. ∎

57
